No reproduction, copy or transmission may be made without written permission from the individual authors.

Review Process
Papers submitted to this conference have been double-blind peer reviewed before final acceptance to the conference. Initially, abstracts were reviewed for relevance and accessibility and successful authors were invited to submit full papers. Many thanks to the reviewers who helped ensure the quality of all the submissions.

Ethics and Publication Malpractice Policy
ACIL adheres to a strict ethics and publication malpractice policy for all publications – details of which can be found here:
http://www.academic-conferences.org/policies/ethics-policy-for-publishing-in-the-conference-proceedings-of-academic-conferences-and-publishing-international-limited/

Self-Archiving and Paper Repositories
We actively encourage authors of papers in ACIL conference proceedings and journals to upload their published papers to university repositories and research bodies such as ResearchGate and Academic.edu. Full reference to the original publication should be provided.

Conference Proceedings
The Conference Proceedings is a book published with an ISBN and ISSN. The proceedings have been submitted to a number of accreditation, citation and indexing bodies including Web of Science and Scopus.

Author affiliation details in these proceedings have been reproduced as supplied by the authors themselves.

The Electronic version of the Conference Proceedings is available to download from https://papers.academic-conferences.org/index.php/eccws

The Conference Proceedings for previous years can be purchased from http://academic-bookshop.com

E-Book ISBN: 978-1-917204-79-8
E-Book ISSN: 2048-8610
Print version ISBN: 978-1-917204-78-1
Print Version ISSN: 2048-8602

Academic Papers

Cybersecurity Management Competencies in Critical Infrastructure Organizations. A Review and Research Agenda
Shehu Abubakar, Hanna Paananen 1-9

MAGNAS: A CCTV Searching Platform for Digital Investigation
Mahra Alameri, Maitha Alnoaman, Noora Alhashmi, Richard Adeyemi Ikuesan 10-17

A Harmonised Dashboard for Smart Home Device Security
Samiah Alghamdi, Steven Furnell, Steven Bagley 18-27

A Multimodal Authorization Approach for Integrated Access Control Process
Shamma Alhameli, Noof Alhammadi, Richard Adeyemi Ikuesan 28-36

Beyond the Dashboard: Unseen Cybersecurity Vulnerabilities Caused by User Behaviour in Connected and Autonomous Vehicles Systems
Dimah Almani 37-45

Cybersecurity in the Era of Quantum Computing and Advanced AI: Emerging Threats and Future Directions
Hisham Alnabulsiyyah, Meteabah Aldawsari 46-51

Audio Deepfake Generation and Detection using Deep Learning for Digital Forensic Analysis
Mahra Alnaqbi, Richard Adeyemi Ikuesan 52-61

Detecting Obfuscated Circumvention Traffic via Anomaly Detection: A Semi-Supervised Approach to Tor Snowflake Identification
Ban Alomar, Zouheir Trabelsi 62-71

Evaluating the Reliability of LLMs in OSINT Investigations: A Friend or Foe?
Errol Baloyi, Nokuthaba Siphambili, Ntomfuthi Ntshangase, Mpho Letshwenyo, Fhatuwani Makharamedzha, Rendani Mmbodi , Ndabezinhle Hlongwane 72-79

Expanding Tactical Cyber Operations for Information-Age Warfare
Archie Bass, Timothy Shives 80-86

A Lightweight Real-time Framework for Detecting Rogue Switches in Wired Local Area Network
Vijay Bhuse, Vijay Prathap, Reddy Kanipakam, Xinli Wang 87-95

Leveraging Open-Source Intelligence to Combat Cryptocurrency Investment Scams
Johannes George Botha, Abraha Berkman, Louise Leenen 96-106

A Knowledge-driven, AI-assisted Cyber Defence Framework for IoMT Remote Patient Monitoring
Kulsoom S. Bughio, David M. Cook, Abdul M. Unar 107-116

MITRE-ATT&CK Integration for Behavioural HARM-based Attack Simulation
Fomotar Nyuykighan Buhnyuy,, Femi Fasunlade, Oluwatobi Fajana, Mmedo Essien 117-125

Cyber Power Through Propagation Control
Gregory Carpenter 126-136

Securing the AI Revolution: A Maturity Framework for Trustworthy and Resilient Software
Jami Carroll 137-145

Apache Daffodil for Network Traffic Validation
Benjamin Cavanagh, Stephen Taylor 146-154

RAG-H: A RAG-Hardened SOC Framework for Trustworthy Threat Intelligence and AI Defence
Daniela Ceraku 155-165

Defending the Cosmos: Honeypot-based Adversary Detection and Emulation System (HADES)
Arnold Chan, Sam Seo, Ady James 166-175

Assessing Non-Kinetic Effects in Support of Military Operations: An Inference-Driven Framework
Bruce Chojnacki, Nicholas Harrell 176-184

Graph Neural Networks on Phase Space Graphs for Cybersecurity
Parker Cole, Ryan Benton, Ralf Riedel, David Bourrie, Becca Clark, Jeffrey McDonald 185-193

AI Supporting Cybersecurity Curriculum
Henry Collier 194-198

Automatically Attacking Software Reverse Engineering AI Agents
Brian Crawford, Justin Phillips, Patrick McClure 199-205

Implementation and Analysis of SS7 Signalling Firewall Research Laboratory
Ahmet Mithat Demirkol 206-212

Analysis of the Use of Module Lattice Key-Encapsulation Mechanism in Delay Tolerant Networks: A Survey
Fábio Moreira dos Santos, Mark G. Reith, Daniel Koranek 213-221

Investigating AI Enabled Attacks and Malware Within Dark Web Ecosystems: An Updated Assessment
William Easttom, William Butler 222-229

Cybersecurity for Military Satellite Systems: Threats, Domains, and Engineering Countermeasures
William Easttom 230-238

Offensive Cyberspace Operations: Operational Logic, Strategic Utility, and Governance in Contemporary Cyber Conflict
William Easttom 239-247

Information Campaigns in Irregular Warfare: A Framework for Expanding the Threshold of Competition
Nick Elekes, Timothy Shives, Michael Richardson 248-254

A Lightweight Automated SQL Injection Testing Tool with Integrated Discovery and Structured Reporting
Olusanjo Olugbemi Fasola, Ugochukwu Onwudebelu, Ibrahim Ismail, Nancy Chinyere Woods 255-263

A Hybrid Cyber Defense Framework for Indonesia's Military Integration into National Cyber Resilience: A Counterfactual Stress-Test
Fibriansyah Fatahillah, Timothy Shives 264-272

Gamified Provocations of Interest for Cybersecurity Awareness
Steven Furnell, James Todd, Lucija Šmid, Simon Castle-Green, Xavier Carpent 273-282

A Systematization of Knowledge on Biomarker Based Encryption Keys
Matthew Gaber, Mohiuddin Ahmed, Al-Sakib Khan Pathan 283-292

Preparing Industry for IIoT: Separate Sensor Networks for Industrial Automation Security
Ricky Green, Ryan Benton, Michael Black 293-302

A Physically Unclonable Function Authentication Protocol to Secure IEEE C37.118 Communications
Taylah Griffiths, Mohiuddin Ahmed, Chadni Islam, Paul Haskell-Dowland 303-312

The CTI Oligopoly's Contractual Firewall: Restrictive Licensing as a Structural Barrier to Collective APT Defence
Raymond Hagen 313-321

The End of Infodemic? The 2021-2024 UN Effort to Ensure the Integrity of Public Information
Teemu Häkkinen, Dominic Saari 322-328

The University of Maryland's Cyber Events Database 2.0: A Systematic Framework for Analyzing Global Cyber Threats
Charles Harry, Devin Entrikin, William Lucyshyn 329-338

Incorporating S.P.I.C.Y. DICOM Polyglot Threats into Cyber Warfare Exercises
Danny "Danhammer" Hetzel, Xavier-Lewis Palmer, Lucas Potter, Nina Alli 339-349

An Integrated Framework for Ransomware Mitigation: A NIST-Aligned Defense Model Linking Cyber Insurance and Risk Management
Li Huang, Kimberly A. Cornell 350-358

Future Smart Devices in Future Digital Environments
Aarne Hummelholm, Pekka Neittaanmäki, Ruth Kaila 359-368

On Definition of Vulnerability Discovery
Simo Huopio, Erno Pasanen 369-376

Balancing Security and Safety: A Look at Emergency Access Solutions for Implantable Medical Devices (IMDs)
Austin James, Veronica Schmitt, Janine Medina, Danny "Danhammer" Hetzel, Lucas Potter, Xavier Palmer 377-387

Toward Better Use of Cyber Threat Models in Defence Environments
Steve Johnson, Erisa Karafili 388-395

Cyber Early Warning System on Security Operations Center
Timo Koskimäki, Jouni Pöyhönen, Martti Lehto, Mika Hållfast 396-404

A Capability-Based Approach to Evaluate and Mitigate Identified Cybersecurity Gaps in Critical Infrastructures
Eetu Jalmari Johannes Laakso, Vesa Kuikka, Kimmo Kaski 405-413

Bayesian Modeling of Uncertainty in Anti-Phishing Training: A Serious Game for Adversarial Email Crafting
Dimitrios Lappas, Diogo Alexandre Silva, Aristeidis Angelos Zoumpakis, Panagiotis Karampelas 414-423

On the Establishment of Trust: Rethinking Trust in the Age of Artificial Intelligence
Christoph Lipps, Siphesihle Sinthungu 424-432

Cognitive Deception: Cognitive Hacking Phenomenon and Cognitive Security
Mikko Luomala, Jyri Naarmala 433-442

Artificial Immune System for Proportionality Assessment in Military Operations
Clara Maathuis 443-451

Proportionality Assessment in Military Operations with Cellular Automation
Clara Maathuis 452-460

System Dynamics Model for Proportionality Assessment in Military Operations
Clara Maathuis 461-468

Deepfake Technology in Social Engineering: Threats, Detection and Defence Strategies
Tanaka Makamure, Daniel Ogwok 469-476

Detecting DDoS Attacks in IoT Healthcare
Eurydice Makena, Sara Sutton 477-482

A Potential Digital Evidence classification model for 5G NFV Environments Using Supervised Machine Learning Algorithms
Sheunesu Makura, Lucas Blanc, Hein Venter 483-493

Immersive Cyber-Verse: The State of Immersive Learning Techniques in Cybersecurity Education in Small Colleges
Sayonnha Mandal 494-501

The Forgotten Stub: Exploring Malicious Use of the PE DOS Header
Sayonnha Mandal, Kshitiz Aryal, William Mahoney 502-508

Cyber and Electromagnetic Activities (CEMA) in a Multi-domain Battlefield
Juha Kai Mattila 509-517

A Hybrid, Transparent Trust and Risk Assessment Framework for Cryptocurrency Exchanges
Bongani Mawhayi, Johnny Botha, Louise Leenen 518-527

An Assessment Methodology for Learning Mission Characteristics
Joshua Meise, Stephen Taylor 528-536

Sridut: Securing Multi-Controller SDN Integrity with State-Aware Multi-Consistency Storage and Provable Convergence
Adir Miller, Avinash Singh, Hein Venter 537-545

Information Ethics & Social Context as Drivers of Cybersecurity Resilience in South Africa's Uneven Digital Landscape
Elekanyani Mukondeleli, Nokuthaba Siphambili, Mmamolele Molema 546-554

From Play to Mobilization: A Sociotechnical Pathway from Youth Gaming Communities to Geopolitical Cyber Operations
Anvesha Nigam, Emma Johansson, Shreyas Kumar 555-561

Enhancing Credit Fraud Detection in e-Payments through Predictive Analytics using Machine Learning: A Scoping Review
Zenande Nondula, Moses Moyo 562-571

I*ntegrating Cybersecurity Risk Management and Business Continuity of Family-Owned Businesses in Anambra State, Nigeria: A Conceptual Model*
Chinwe Gloria Obananya, Paschal Anosike, Chidimma Odira Okeke 572-578

Enhancing Cybersecurity Resilience in the Real Estate Industry: Mitigating Phishing and BEC Attacks
Oludolamu Ademola Onimole, Etinosa Imafidon, Denzel Pryor, Lucas Potter, Xavier Palmer 579-588

Exploring Personalized Personnel Protection within Cybersecurity
Oludolamu Ademola Onimole, Austin James, Denzel A. Pryor, Angel-Khalil Jones, Xavier Palmer, Lucas Potter, Jude Osamor 589-599

Mapping the Authentication Landscape: A User-Centric View
Hanna Paananen, Naomi Woods, Steven Furnell 600-606

Predicting Sabotaged Open-source Libraries
Alexander Petty, William Glisson, Ryan Benton 607-615

Privacy Under Pressure: Assessing Online Commercial Surveillance Countermeasures and Gaps
Christian Preti, Nicholas Harrell, Alexander Master 616-625

From Evidence to Decisions: Interview-Based Study of Reporting Practices in Defensive Cyber Operations
Justin Raynor, Bijesh Shrestha, Cody Dunne, Melanie Tory, Lane Harrison 626-635

Cybersecurity Entry Points to the Energy Sector and Their Time-To-Compromise
Engla Rencelj Ling, Göran Ericsson 636-644

Digital State Erasure: Data as Both a Target and a Vector of Political and Military Influence
Mari Ristolainen, Veikko Siukonen 645-652

A Framework for Privacy-Preserving Data Analytics Using Differential Privacy
Huwida E. Said, Qusay H. Mahmoud, Neema Prakash, Asma Almarzooqi 653-663

LLM-Assisted Forensic and Compliance Auditing for Public Sector Organizations
João Santos, Rodrigo Correia, Jesús Betancourt, Tiago Cruz, João Henriques, Filipe Caldeira, Paulo Simões 664-671

What Motivates Cyberattacks: Lack of Consequences or Abundance of Attack Vectors?
Matthias Schulze, Florian Erdle 672-681

Testing ML-KEM Implementations for Side-Channel Vulnerability: The Airtight Framework
Isaiah Seals, Douglas Hodson, Mark Reith 682-690

Satellite Cyber Security Assurance Framework – Assured Unified SPARTA-COSMOS2 Assessment Notation (AUSCAN)
Sam Seo, Jill Slay 691-699

A Framework for Automated STIG Compliance for Navy Ships
Margaret Graves, Alan Shaffer, Gurminder Singh 700-707

Beyond Missiles and Marines: A Multidomain Strategy for Deterring a PRC Invasion of Taiwan
Timothy Shives, Rose Kingham 708-714

Operationalizing Cyber in Multi-domain Operations: A Kill-Chain- Centric Approach for Cyber Strike Packages
Timothy Shives, William Stegner, Elizabeth Pham, Lieuwe Jan Hiemstra 715-725

Toward Identifying Role-Aligned AI Governance Needs in Mixed-Trust Environments
Bijesh Shrestha, Nicholas Harrell, Matthew Corbett, Michael Quigg 726-735

Data Governance Frameworks for Enabling Responsible AI in Small, Medium, and Micro Enterprises: A Systematic Literature Review
Nokuthaba Siphambili, Norman Nelufule 736-744

A Double-Edged Sword: How Lab Cameras may Enable Cyber Deception in Biosecurity
Rachid Soro, Lucas Potter, Xavier Palmer, Michaela Barnett 745-753

Targeting the Human Factor: OSINT in Healthcare
Marie Soukupová 754-760

Lost at Sea: GPS Spoofing Threats to Maritime Shipping
Sandali Srivastava, Shaunak Srivastava, Nithya Vemuri 761-767

Significance of Biological Design-based Strategies Towards Sustainability and Security in Space Biology Research: A Partial Taxonomy and Exploration
Aswati Subramanian, Xavier-Lewis Palmer 768-774

Hybrid Threats against the Finnish Society: Reported by YLE News
Ilkka Tikanmäki, Jarmo Heinonen, Harri Ruoslaht 775-781

ECUInjector: An Automotive ECU Security Analysis Tool
James Todd, Aidan Grant, Tim Muller, Xavier Carpent 782-791

Officers' Perceptions on Cyberwarfare Enhanced with Artificial Intelligence
Maija Turunen, Maria Keinonen 792-799

Intrusion Detection System for Software-defined Satellite Networks
Uakomba Uhongora, Mamello Thinyane, Yee Wei Law, Jill Slay 800-809

Supervised Classification of Cloud Workload Behavior Using Out-of-Band Performance Metrics
Maureen Van Devender, Thanh Le, Ryan Benton, Angela Buie, Ralph Mouawad, Zoe Steele 810-821

Social Engineering of AI Agents
Jukka Vuorinen, Eeli Mäkinen 822-830

Cyber Security at Universities: Comparison of Australia, Lithuania and Ukraine
Matthew Warren, Marius Laurinaitis , Michael Prazian 831-837

Digital Sovereignty and Cross-Border Compliance in Internet Governance
Murdoch Watney 838-845

AI to AI Autonomous Cyber Warfare: Ethical and Anticipated Ethical Issues
Richard Wilson, Noah Donnelly 846-854

Artificial Intelligence, Drones and Cyber Warfare: Ethical and Anticipated Ethical Issues
Richard Wilson, Noah Donnelly 855-863

AI, Urban Warfare and Cyber Warfare: Ethical and Anticipated Ethical Issues
Richard Wilson, Noah Donnelly 864-871

The Baseband Sovereignty Paradox: Anticipated Ethical and Technical Issues of Baseband Processors
Richard Wilson, Noah Donnelly 872-879

Forever Days, Silicon Immutability and the Crisis of Unpatchable BootROM Vulnerabilities in Cyberwarfare: Ethical and Anticipated Ethical Issues
Richard Wilson, Noah Donnelly 880-888

Weaponizing Firmware, Cyberwarfare and Battery Management Systems: Ethical and Anticipated Ethical Issues
Richard Wilson, Noah Donnelly 889-896

The Military Tech Complex and Cyberwarfare: Ethical and Anticipated Ethical Issues
Richard Wilson, Noah Donnelly 897-905

Trustworthy Secure and Measured Boot on a Raspberry Pi 4
Torben Woltjen, Michelle Jakobi, Michael Eckel, Janik Gorbracht, Richard Sethmann 906-914

Disinformation and Trust in digital environments: Expert decision-making, dismiss or discuss?
Allison Wylde, Fabio James Petani, Helmi Issa, Fortuna Cassoria 915-921

NEXUS-HC: A Framework for Technology Foresight in Strategic Communications
Yukai Zeng 922-930

PhD Papers

Systematically Integrating Cyber Threat Intelligence into Resilient Space-Cyber Architectures
Chathura Abeydeera 932-942

'What's in a Name?': How Does the UK Government and Media Construct Cyber Actors?
Alice Brett, Iain Reid 943-949

Beyond Obscurity: Developing CubeSat Cybersecurity
Joshua Davis, Jill Slay, Nalin Arachchilage 950-957

Zero-Day Vulnerabilities, Cartography, and Quantification Initiative
Myriam Ouraou 958-967

Masters Papers

Warfare in the Gray Zone: The Need for a Western Paradigm Shift
Austin Carter, Timothy Shives 969-975

Banking Resilience: Building Cyber Incident Response in the Finnish Financial Sector
Jade Karrila, Ilona Ilvonen 976-983

AI Warfare
Dong Wang, Tokunbo Makanju, Yunlong Shao 984-993

Non-Academic Papers

Building Cyber Defenders of the Future: Curriculum Design for Emerging Roles
Toby Meyer, Austin Vershave, Jael Rivera 995-1003

Work in Progress Papers

Towards a Resilience Framework for Securing ADS-B Surveillance Systems in Air Traffic Management
Victoria Mofolo 1005-1008

AI Safety Under Uncertainty: Hallucinations and Unpredictable Failures
Joon Park 1009-1011

Compliant Cyber Threat Intelligence Sharing in Hospitals: Evaluating the Data Anonymisation Tool
Ilkka Tikanmäki, Ammar Alhamada, James Lukins, Retina Nerjovaj, Marco Pastore, Lauri Pöllänen 1012-1015

Enhancing Cybersecurity in Water Plant Infrastructure with SecureAI
Ilkka Tikanmäki, Diana Marinca, Muhibba Saani Muhammed, Rakyan Kadar Slamet 1016-1019

Privacy-Preserving Cyber Threat Intelligence Sharing in Healthcare: Automated Anonymisation Under EU Regulations
Ilkka Tikanmäki, Lillebi Seistola, Harri Silvola, Pihla Parviainen 1020-1023

The Future of Authentication: Not as Simple as Providing a Secure Solution
Naomi Woods, Hanna Paananen 1024-1026

No Rules: Can Removing Password Creation Rules Improve Password Memorability and Security?
Naomi Woods 1027-1030

Late Submissions

Securing the Decentralized Edge: An Integrated Approach to Endpoint Security Monitoring and Threat Detection
Victor Bungei, Frank Johnfia, Esther Djan, Sara Sutton 1032-1041

The Weaponization of the Marketing Funnel: Adapting Commercial Targeting Strategies for Disinformation Campaigns and Troll Detection
Petr Gallus, Dominik Staněk, Tomáš Ráčil, Willi Lazarov, Ivo Klaban 1042-1050

Reviewing Machine Learning Algorithms for Threat Detection in Cybersecurity
Aidan Gatenbee, Mark Reith, Anthony Rose 1051-1056

Strengthening Analytical Competence in (Cyber) Intelligence
Gazmend Huskaj, Stefan Axelsson 1057-1065

Cyber Warfare, Cyberbullying and Psychological Warfare: Ethical and Anticipated Ethical Issues
Richard Wilson, Noah Donnelly 1066-1074

Libraries as Frontline Defenders Against Disinformation Warfare: Fact or Fiction?
Edmont Pasipamire 1075-1083

25th European Conference on Cyber Warfare and Security, 2026

The European Conference on Cyber Warfare and Security (ECCWS) is a distinguished academic conference that has been held annually for 25 years, attracting a global audience of scholars, researchers, military professionals, and industry experts. The conference is dedicated to advancing knowledge and understanding of cyber warfare and cybersecurity through the presentation and discussion of high-quality, peer-reviewed research.

The Proceedings of the 25th European Conference on Cyber Warfare and Security, 2026 includes academic research papers, PhD research papers, Master's Research papers and work-in-progress papers which have been presented and discussed at the ECCWS 2026 conference. The proceedings are of an academic level appropriate to a professional research audience including graduates, post-graduates, doctoral and post-doctoral researchers. All papers have been double-blind peer reviewed by members of the Review Committee.

Aims and Scope

ECCWS provides a comprehensive platform for the exploration and discussion of the complex and evolving challenges in the fields of cyber warfare and cybersecurity. It seeks to bridge the gap between academic research, practical applications, and policy-making, fostering interdisciplinary collaboration and the exchange of ideas. The conference focuses on both theoretical and applied aspects of cybersecurity and cyber defence, with an emphasis on the implications for national security, military strategy, and global stability.

Topics Covered

The call for papers for the ECCWS conference asked for contributions that considered the following topics. In addition, the committee welcomed papers on a number of specialist mini-tracks which can be seen at the end of this list.

Cyber Warfare Strategies and Tactics
- *Offensive Cyber Operations*
- *Defensive Cyber Operations*
- *Cyber Deterrence and Cyber Power.*

Cyber Defence and Security
- *Threat Detection and Incident Response*
- *Security Architectures*
- *Vulnerability Assessment and Management including pentesting*

Cyber Threat Intelligence
- *Adversary Tactics, Techniques, and Procedures (TTPs)*
- *Threat Intelligence Sharing*
- *Advanced Persistent Threats (APTs).*

Critical Infrastructure Protection
- *Protection of Energy, Water, and Transport Systems*
- *Financial Sector Security*
- *Telecommunications Security*

Military Applications of Cyber Technologies
- *Cyber Command and Control Systems*
- *Cyber-Physical Systems in Defence*
- *Information Warfare and Psychological Operations.*

Legal and Ethical Issues in Cyber Warfare
- *International Law and Cyber Conflict*

- *Ethical Dilemmas in Cyber Operations*
- *Cyber Espionage and Sovereignty.*

Emerging Technologies and Innovations

- *Artificial Intelligence in Cybersecurity*
- *Quantum Computing and Cybersecurity*
- *Blockchain for Cybersecurity*

Cybersecurity Education and Training

- *Military Cyber Training Programs*
- *Cybersecurity Curriculum Development*
- *Capacity Building in Cybersecurity*

Policy, Governance, and International Cooperation

- *National Cybersecurity Strategies*
- *International Cyber Norms and Agreements*
- *Public-Private Partnerships in Cybersecurity*

Cybercrime and Law Enforcement

- *Digital Forensics*
- *Countering Cybercrime*
- *Legal Frameworks for Cybercrime*

Experts in the field proposed mini tracks on the following topics. Papers accepted on these topics after the double-blind peer review process were presented as mini tracks at the conference and are also published in these proceedings.

- *Software Supply Chain Security Risks*
- *Smart Systems Under Siege: Analyzing Cybersecurity Risks and Real-World Incidents*

The programme from the 2026 conference can be downloaded from https://papers.academic-conferences.org/index.php/eccws and full details about the conference can be seen from the conference website: https://www.academic-conferences.org/conferences/eccws/

ECCWS Preface

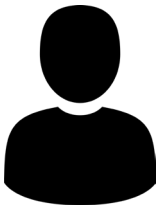
These proceedings represent the work of contributors to the 25th European Conference on Cyber Warfare and Security (ECCWS 2026), Hosted by the University of Nottingham, UK on 29-30 June 2026. The Conference Co-Chairs are Steven Furnell from the University of Nottingham, UK, and Dimah Almani, from Shaqra University, Saudi Arabia.

ECCWS is a well-established event on the academic research calendar and now in its 25th year conference remains the opportunity for participants to network and share ideas. The following conference proceedings contain a diverse range of papers, and the conference continues to be a forum for technical, theoretical and practical exchange about the study, management, development and implementation of systems and concepts to improve cyber security and combat cyber warfare.

The opening keynote presentation is given by Dr Lorna Kirkby, Department for Science, Innovation and Technology of the UK Government on the topic of *Securing the Digital Future: The UK Government's Approach to Cyber Security.* The second day of the conference will open with an address by Prof. Adam Joinson, from the University of Bath, UK speaking on the *Mapping the Impact of Future & Emerging Technologies on Cybersecurity.*

With an initial submission of 190 abstracts, after the double blind, peer review process there are 109 Academic research papers, 4 PhD research papers, 3 Masters Research papers, 1 Non-Academic Paper and 7 work-in-progress papers published in these Conference Proceedings. These papers represent research from Australia, Canada, Czech Republic, Finland, France, Germany, Greece, Netherlands, Nigeria, Norway, Pakistan, Portugal, Saudi Arabia, Singapore, South Africa, Sweden, Switzerland, Turkey, UK, United Arab Emirates, and USA.

We hope you enjoy the conference.



Steven Furnell and Dimah Almani
Conference Co-Chairs
Nottingham, UK
June 2026

Biographies of Chairs and Keynote Speakers

Conference and Programme Chairs

Prof. Steven Furnell is Professor of Cyber Security in the School of Computer Science at the University of Nottingham. His research interests include security management and culture, usability of security and privacy, and technologies for user authentication and intrusion detection. He has authored over 400 papers in international journals and conference proceedings, as well as various books, book chapters, and industry reports. Steve is the UK representative to Technical Committee 11 (security and privacy) within the International Federation for Information Processing, a board member of the Chartered Institute of Information Security, and a member of the Steering Group for the Cyber Security Body of Knowledge (CyBOK) and the Careers and Learning Working Group within the UK Cyber Security Council.

Dr. Dimah Almani completed her PhD in Cybersecurity at the University of Nottingham, specialising in trust mechanisms for vehicle-to-vehicle (V2V) communication. Her research focused on improving security in connected vehicles using simulation tools such as Veins, SUMO, and OMNeT++. She also holds a Master's degree in Computer Science from Nova Southeastern University, Florida, where she investigated cybersecurity vulnerabilities in smart transportation systems. With over 10 years of teaching experience, Dimah has developed and delivered courses on emerging technologies, supervised postgraduate students, and contributed to cybersecurity research. She is skilled in C++, Python, and MATLAB, with strong knowledge in network simulations and mathematical modelling. Dimah has served as an IEEE reviewer and held academic leadership roles including Coordinator of Quality Control and E-Learning Program Manager. She received the IBM Artificial Intelligence Analyst – Explorer Award in 2020. Her work connects theoretical models with real-world applications in cybersecurity and intelligent transportation systems.

Keynote Speakers

Dr Lorna Kirkby is Head of Software Security Policy for the Department for Science, Innovation and Technology. This includes leading work to develop the UK government's Software Security Code of Practice and how to drive uptake of these principles throughout digital supply chains as part of the Government's longstanding advocacy of a secure by design approach to technology development.

Adam Joinson is Professor of Information Systems at the University of Bath. Adam has been working on the intersection between behavioural science, technology and security for over 25 years, including seminal work that helped establish 'cyberpsychology' as a field of study. He has also worked in Government applying behavioural science to security, and has led multiple large scale research programmes. He is co-director of the Bath Institute for Digital Security and Behaviour (www.idsb.ac.uk) as well as co-investigator on the EPSRC CRANE Network Plus (www.crane.ac.uk). His website is: https://researchportal.bath.ac.uk/en/persons/adam-joinson/

Mini Track Chairs

Dr Hossein Abroshan is a cybersecurity researcher focusing on adversarial machine learning and applied AI for cyber defence. His recent work includes building AI poisoning-detection pipelines; developing AI-driven ransomware detection for OT; and AI-powered phishing detection using human factors. He has also developed AI and cybersecurity materials for CyBOK (ai4cs.uk and secai.uk). Hossein is the director of cybersecurity research group and director of MSc Cyber Security course at ARU, Cambridge, and has been leading/supervising several cybersecurity and AI projects in various sectors. Hossein's interests include AI security and trustworthy AI, human factors in cyber security, and protection of critical infrastructures.

Tiago Cruz is Associate Professor at the Department of Informatics Engineering of the University of Coimbra. He is a Senior Researcher at the Center for Informatics and Systems of UC, having started his research activity in 2001. His research interests cover areas such as management systems for communications infrastructure and services (operator and data center environments), embedded computing, critical infrastructure security, broadband access network device and service management. He has been involved in various European- and industry-funded research projects related with cyber-security, autonomous management, content delivery infrastructures or wireless WAN technologies, as well as several national projects, in partnership with telecommunications operators and research agencies, with both technical and management activities.

Christoph Lipps, graduated in Electrical and Computer Engineering at the University of Kaiserslautern, where he meanwhile lectures as well. He is a Senior Researcher at the German Research Center for Artificial Intelligence (DFKI) in Kaiserslautern, Germany, heading the Cyber Resilience & Security Team of the Intelligent Networks Research Department. His research focuses on Physical Layer Security (PhySec), Physically Unclonable Functions (PUFs), Artificial Intelligence (AI) Methods, Security and Trust in the Sixth Generation (6G) Wireless Systems and all aspects of network and cyber security. He is the author of numerous scientific publications, member of the IEEE, ACM and VDE, as well as of the scientific advisory boards and technical program committees of multiple international conferences and journals.

Iain Reid is a Senior Lecturer in Cybercrime in the School of Criminology and Criminal Justice at the University of Portsmouth in the UK. He is an Expert Fellow of SPRITE+, Member of SASIG, and was previously a Founding Committee Member of the Defence and Security Psychology Section. In addition, Iain is the Course Leader for the Professional Doctorate in Security Risk Management and is the Cybercrime and Cybersecurity Research Group Lead. Iain's research interests focus on defensive cyber deception, software development and security, cyber conflict, and lie detection

Char Sample is an assistant professor of cybersecurity at Marshall University. Dr. Sample has 40 years of industry experience beginning in software development, through product test and integration, and finally as a researcher (both applied and academic). Dr. Sample's research areas are all cybersecurity related with an interest toward decision-making in cybersecurity.

Paulo Simões is Associate Professor at the Department of Informatics Engineering of the University of Coimbra, Portugal. He is also a senior researcher at the Centre for Informatics and Systems of the University of Coimbra. He has more than 15 years of experience in European research projects (FP6, FP7, H2020, COST…), with technical and managerial duties, and he regularly leads industry-funded technology transfer projects for companies such as telecommunications operators and energy utilities. His research interests include Network and Infrastructure Management, Security, Critical Infrastructure Protection and Virtualization of Networking and Computing Resources. He has over 160 publications in refereed journals and conferences, and he regularly serves on program committees of international conferences of these areas. He is also Senior Member of the IEEE Communications Society.

Jill Slay is currently the University of South Australia SmartSat Professorial Chair in Cybersecurity. Her work focuses on the context of developing a national technical agenda in satellite cybersecurity and resilience with Industry and government. Previous appointments have included Optus Chair in Cybersecurity at La Trobe University and Founding Director of the Australian Centre for Cyber Security at the Australian Defence Force Academy.

ECCWS Review Committee

ECCWS is fortunate to have a significant number of international experts in the field willing to review papers. Care is taken to ensure that a fully double-blind peer review process is followed, and reviewers are not selected if they have any research or organisational connection to the author/s.

Cybersecurity Management Competencies in Critical Infrastructure Organizations: A Review and Research Agenda

Shehu Abubakar and Hanna Paananen
University of Jyväskylä, Finland

Shehu.s.abubakar@jyu.fi
hanna.k.paananen@jyu.fi

Abstract: Critical infrastructure is vital to the economic, social, and technological survival and welfare of nations. Attacks on these infrastructures can be devastating and can lead to serious consequences. The Top Management Team (TMT) is the highest decision-makers who seal the fate of such organizations when it comes to risk management. Regulations and best practices are demanding that the TMT take responsibility for the cybersecurity posture of the critical infrastructure organizations to protect that infrastructure or prevent further damage. Critical infrastructure organizations often have a combination of information technology and operational technology spread across a wider geographical area and extensive regulation that can affect security investments and the TMT composition. Consequently, to effectively carry out their responsibilities, the TMT requires cybersecurity competencies; therefore, the specific cybersecurity management competencies that constitute these requirements need to be identified and tailored to their roles. To identify research in this area, we surveyed prominent journals that publish on cybersecurity, management, and critical infrastructure. We used search terms that address cybersecurity skills, knowledge, and attitudes necessary for top management in strategic decision-making and cybersecurity risk management. To ensure the collection of relevant articles, the literature review follows a systematic review process. A qualitative analysis method was employed to identify five thematic areas, namely leadership, learning, organization, cybersecurity, and competency, through which management's cybersecurity competencies are positioned as strategic requirements that can impact organizational cybersecurity resilience. The strategic responsibilities of the Top Management Team (TMT) are interestingly extending to cybersecurity management in organizations. They are also required to align cybersecurity management with the organization's strategic objectives. Thus, to effectively carry out their responsibilities, the TMT requires cybersecurity competencies. This review has identified relevant cybersecurity skills, knowledge, and attitudes that can be constituted as cybersecurity management competencies that will support TMT in the critical infrastructure protection. The review also reveals research gaps due to the limited number of studies conducted considering the entire TMT cybersecurity management competencies. This review provides a foundation for developing a theoretical framework for studying TMT cybersecurity competencies in critical infrastructure organizations.

Keywords: Cybersecurity, Senior management, Competencies, Critical infrastructure

1. Introduction

Critical infrastructures are consistently faced with an increasing number of attacks. Attacks or disruptions to critical infrastructure can prove disastrous and can negatively affect their reliability and safety (Alcaraz and Zeadally, 2015) with the effect going beyond one national border to another (Lehto, 2022).

These attacks may result in extremely high revenue losses (He et al., 2018), and financial loss is not the only adverse effect can also lead to legal liabilities with serious repercussions (Dynkin and Dynkin, 2018). These attacks are on the rise and are causing losses of billions of dollars (Cremer et al., 2022), as well as loss of market capitalization (Mukhopadhyay *et al.*, 2019). Consequently, directors are more likely to be held responsible when organizations experience attacks (Frank, Grenier and Pyzoha, 2021). Thus, the senior leadership is critical in ensuring responsible cybersecurity within organizations (Panteli, Nthubu and Mersinas, 2025).

The Top Management Teams (TMTs) play a central role in daily operations and are responsible for strategic decisions (Bendig et al., 2023), with cybersecurity being one of their major responsibilities (Li et al., 2018). TMT is duty-bound to ensure effective cyber risk management (Radu & Smaili, 2022). They need to possess cybersecurity knowledge, competence, and skills (Garcia-Granados & Bahsi, 2020). Delegating cybersecurity risk management to the IT department has proven insufficient (Rothrock & Kaplan, 2018). However, many leaders remain inadequately equipped with a technical background for the tasks (Gale et al., 2022).

Various methods and techniques have been developed to enhance cybersecurity awareness among the TMT (Taherdoost, 2024). While awareness aims to instil a proactive attitude toward cybersecurity, skills provide the necessary tools for maintaining security hygiene (Haney & Lutters, 2020). However, their training and awareness programs have received limited scholarly attention, and many remain unaware of key threats (Vrhovec & Markelj, 2024). Moreover, memory retention from an awareness program tends to be short-lived (Ghafir et al., 2018). The lack of sustainable cybersecurity programs within organizations is a recurring concern (Akter et al.,

2025). Additionally, there is no consensus on the metrics for measuring the effectiveness of cybersecurity awareness programs for TMT (Chaudhary et al., 2022).

Chowdhury & Gkioulos (2021b) conducted a literature review of 29 papers addressing workforce knowledge, skills, and competencies. TMT competencies have not been specifically explored in reviews, except for the finding that managers and top executives hold the mandate to ensure effective implementation of cybersecurity measures in their organizations (Vidgren, 2020). This highlights the research gap concerning cybersecurity competencies in top management.

This literature review seeks to answer the following question:

What cybersecurity management competencies have been identified that support TMT strategic responsibilities for cybersecurity management in critical infrastructure organizations?

The paper is structured as follows: Section two defines key concepts, including the top management team, competence, and cybersecurity management competence. Section three outlines the review methodology. Section four presents the findings. Section five discusses the results, and Section six concludes the paper.

2. Key Concepts

2.1 Top Management Team

Numerous academics have examined the concept of the Top Management Team (TMT), they are organization's senior officers (Carpenter, Geletkanycz and Sanders, 2004). TMT are the top senior officers who make and participate in strategic decisions (Amason, 1996). According to Menz (2012a) TMT consists of senior executives with one or more functional responsibilities. They represent the highest and second-highest levels of executive management (Wiersema, 1992). TMT exerts a significant influence on strategy formulation (Nielsen, 2010). They are also responsible for planning and executing strategies (Wu *et al.*, 2017), and are recognized as the senior executives who manage the organization's business (Gao, Wattal and Thatcher, 2025).

Li et al., (2022) identified members such as the chief executive officer, chief financial officer, vice president, general manager, chief executive deputy general manager, and vice manager. Increasingly, the chief information security officer has been included in the TMTs due to growing concerns about cybersecurity (Gao, Wattal and Thatcher, 2025). Other roles include the chief information officer (Bendig *et al.*, 2023), chief technology officer (Gu, Wang and Mai, 2024), chief information officer, chief strategy officer, chief knowledge officer, chief operations officer, and chief marketing officer (Menz, 2012b).

2.2 Competency

The term competence has attracted significant interest in organizational management (Salman, Ganie and Saleem, 2020). Researchers from education, psychology, human resources, management, politics, and information systems have aligned its meaning within their respective fields (Hoffmann, 1999; Bassellier, Benbasat and Reich, 2003). Consequently, competence lacks a universally accepted definition (Jubb and Robotham, 1997). Nonetheless, it continues to be applied across different perspectives

It is viewed as a combination of skills, performance, personal traits, or knowledge essential for the effective delivery of a role (Brophy and Kiely, 2002). It represents the potential that leads to effective behavior and the capability of an individual to perform successfully in a specific role (Anderson, Ahmad and Chang, 2024a). Individual competence contributes to the organization's core competence (Bassellier, Reich and Benbasat, 2001). Blömeke et al. (2015 p. 4) ''criterion behavior as well as the knowledge, cognitive skills, and affective-motivational dispositions that underlie that behavior." More broadly, it reflects the behavior of an entity that enables effective performance in its role (Woodruffe, 1993).

3. Method

To ensure the collection of relevant articles, the review follows the framework proposed by Okoli (Okoli, 2015) which includes the following steps: I) establishing the purpose of the literature review, II) protocol, III) searching for literature, IV) practical screen, V) quality appraisal, VI) data extraction, VII) synthesis of studies, and VII) writing the review.

3.1 Purpose of the Literature Review

The objectives of this literature review are to identify and analyze articles on the cybersecurity competencies of the top management team (TMT) in CI organizations as follows:

- Identify papers published in top information systems, cybersecurity, and critical infrastructure outlets that address cybersecurity competencies necessary for top management in strategic decision-making and cybersecurity management
- Analyze and evaluate the identified research articles to summarize findings related to TMT cybersecurity competencies in critical infrastructure organizations.
- Reveal research gaps concerning cybersecurity competencies of the top management team in the CI organizations.

3.2 Protocol and Literature Search

We conducted a literature search on 14 journals with the search terms: (cybersecurity OR "Information Security") AND ("Top Management" OR "senior management" OR "executive officers") AND ("Critical Infrastructure"). We used the databases Web of Science, Scopus, and Google Scholar, as well as direct searches of the listed journals. The initial search yielded: Google Scholar = 256, Scopus = 71, and Web of Science = 3, for a total of 330 articles. This number was significantly lower than expected. Therefore, to increase the likelihood of finding more relevant articles, a direct search in the chosen journals was conducted. These methods yielded an additional 698 articles; combined with the 330 articles from Google Scholar, Web of Science, and Scopus, a total of 1,028 articles were selected.

3.3 Practical Screening

During practical screening, papers were selected based on their title, abstract, year of publication 2003-2025, discussion, results, and summary, English language, setting related to TMT cybersecurity competency, and Senior Management staff as participants or subjects. Papers that focused on only technical aspects of cybersecurity were excluded.

3.4 Quality Appraisal

Initially, only papers matching the keywords in their titles or abstracts were selected. A total of 104 papers from the journals met these criteria.

Table 1: List of additional papers through forward and backward searches

SN	Forward	Cited	Backward	From the Ref. List
1	(Jewer and McKay, 2025)	(Bassellier, Benbasat and Reich, 2003; Benaroch and Chernobai, 2017; Haislip, Lim and Pinsker, 2021)	(Puhakainen and Siponen, 2010)	(Barton *et al.*, 2016)
2	(Onibere, Ahmad, and Maynard, 2017)	(Ashenden and Sasse, 2013)		
3	(Anderson, Ahmad, and Chang, 2022)	(Ashenden and Sasse, 2013)		

The second selection process resulted in 31 papers that met the criteria. In addition to this selection, backwards searches produced 1 paper and forward searches yielded 3 papers, as indicated in the table above.

Thematic analysis was adopted with inductive coding; therefore, themes are derived based on what the data "tell us".

3.5 Leadership

Strategic cybersecurity leadership comprises executives and managers - the top management team – identified in the literature as those responsible for cybersecurity risk management, governance, and compliance. Their strategic roles influence the organization's cybersecurity risk posture, culture, and resilience. The literature indicates that senior management plays a highly instrumental role in cybersecurity risk decision-making activities (Ashenden and Sasse, 2013; Onibere, Ahmad and Maynard, 2017; Benaroch and Fink, 2021; Haislip, Lim and Pinsker, 2021; Bendig *et al.*, 2022; Shillair *et al.*, 2022; Lorenz and Buchwald, 2023; Jewer and McKay, 2025; Sahin and Vance, 2025)

Several articles have viewed cybersecurity strategic responsibilities as resting on cybersecurity managers and leaders, such as the CTO, CIO, and CISO (Ashenden and Sasse, 2013; Onibere, Ahmad and Maynard, 2017; Kappelman *et al.*, 2019; Anderson, Ahmad and Chang, 2022; Bendig *et al.*, 2022; Ramezan, 2025; Sahin and Vance, 2025), despite the limited access of CISOs to the board (RenÃ, 2022). Furthermore, the inclusion of the CIO in the C-suite is being misunderstood (Bendig *et al.*, 2022).

3.6 Organization

Organizational objectives, strategies, and policies should align with cybersecurity readiness, as security improves when cybersecurity goals are integrated with broader organizational objectives (AlGhamdi, Win and Vlahu-Gjorgievska, 2020; Anderson, Ahmad and Chang, 2022). In practice, the responsibilities of the TMT to their organizations in ensuring effective information security governance and leadership accountability can strengthen the organization's security posture (AlGhamdi, Win and Vlahu-Gjorgievska, 2020; Alshaikh, 2020; Shillair *et al.*, 2022). We found strong connections between the organizational objectives and cybersecurity strategic alignment, and leadership (Onibere, Ahmad and Maynard, 2017; Anderson, Ahmad and Chang, 2022). Additionally, differences in the organizational levels affect cybersecurity management: large and small organizations have boards (Anderson, Ahmad and Chang, 2022) SMEs may face constraints due to limited resources (Almeida, 2025). Evidently, large organizations usually have a dedicated person in charge of cybersecurity, while small organizations may not (Kappelman *et al.*, 2019)

3.7 Cybersecurity

Cybersecurity management comprises a range of roles (Almeida, 2025) that require defense against threats and defense against cyber threats is one of the cybersecurity strategic goals (AlDaajeh *et al.*, 2022), which falls within the purview of the top management (Shillair *et al.*, 2022). Consequently, leaders need to adapt strategies in combating these evolving cyber threats (Anderson, Ahmad and Chang, 2024b).

This theme reflects the continuously evolving nature of cyber threats, vulnerabilities, and risks, along with the corresponding responsibility of the top management to ensure information security governance for organizational success (AlGhamdi, Win and Vlahu-Gjorgievska, 2020), and determination of response to cyber threats (Shillair *et al.*, 2022). The core of this theme highlights how TMT addresses, manages, and responds to cybersecurity practices. Since information security needs to be addressed at the strategic level (Almeida, 2025), this study underscores the critical role of the TMT in addressing these cybersecurity risks.

3.8 Learning

The theme learning focuses on the various education, training, and awareness initiatives adopted by organizations, especially CI organizations, to ensure employees acquire skills, knowledge, and competencies needed to fulfill their responsibilities. Security education, training, and awareness (SETA) has been widely seen to be one of the learning paths to increase cybersecurity culture . Anderson et al. (2022) reported that the SETA program can be seen to be a marketing plan rather than an educational one, and an awareness program for top management has been identified as one of the cybersecurity critical success factors for organizations (Yeoh *et al.*, 2022). However, no literature was found that specifically identifies a learning program mapped to the entire TMT based on its strategic positions, composition, and commitments.

3.9 Competence

Technical competencies or hard skills are typically associated with cybersecurity professionals (Onibere, Ahmad and Maynard, 2017; Furnell, 2021; Anderson, Ahmad and Chang, 2022) . Then again, competencies such as communication skills, risk management, and incident response (Anderson, Ahmad and Chang, 2022, 2024b) are identified as essential in organizational cybersecurity management processes.

The leadership and cybersecurity themes are linked through TMT's strategic responsibilities. For example, AlGhamdi et al.(2020) acknowledged the importance of the TMT in the success of information security. Haislip et al., (2021) emphasized IT governance and (Shillair *et al.*, 2022) highlighted the importance of top management involvement in responding to cyber threats. Connections between leadership and competencies (Furnell, 2021; Anderson, Ahmad and Chang, 2022; Ramezan, 2025) are crucial for top management in carrying out their responsibilities. Some are intended for cybersecurity leaders in general (Anderson, Ahmad and Chang, 2022) or for technical TMT members such as CISOs (Ramezan, 2025) Anderson et al. (2024) Focus on case-based learning to support cybersecurity leaders in their roles and emphasize pedagogical learning accordingly. Additionally, Alshaikh, (2020) reported alignment of cybersecurity awareness with an external campaign, identification of

cybersecurity behaviours, establishment of a cyber champion network, and development of a brand for the cyber team.

3.10 Synthesis

The literature includes works that consider competencies aiding in supporting top management in discharging their cybersecurity strategic responsibilities in Ci organizations. For example, A. B. Anderson et al. (2022) identified several cybersecurity competencies that include skills, knowledge, and attitudes. However, the identified competencies are found to be tailored to cybersecurity leaders. Similarly, Furnell (2021) identified various cybersecurity competencies mapped to the technical members of the TMT. Figure 1 highlights the identified connections among the themes.

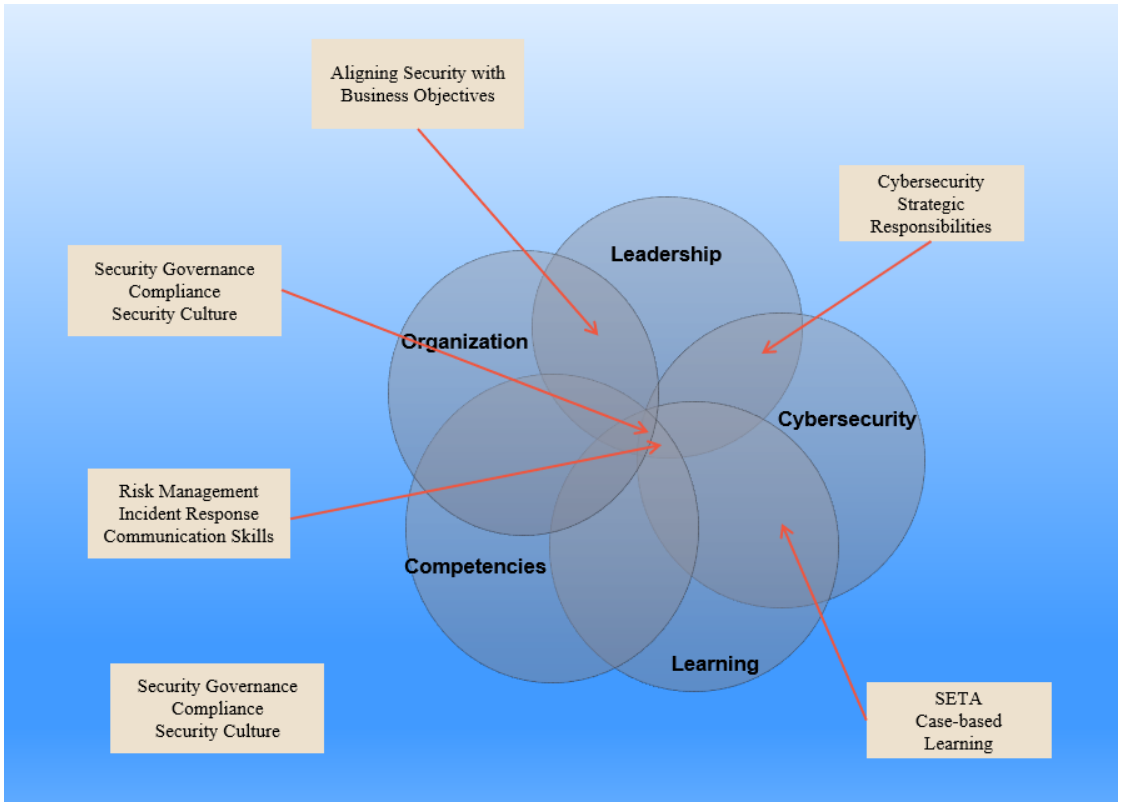

Figure 1: Connections between the identified themes

The study identified the following competencies in Table 2.

Table 2: Summarized connections among the themes

Source	Competency	Rationale
(Anderson, Ahmad, and Chang, 2022) and (Anderson, Ahmad, and Chang, 2024b)	Communication skills	For intra- and inter–team communication and discussions on cybersecurity activities, to enable members to develop a common understanding of terminologies in the decision-making process
	Risk management	To facilitate their cyber risk management decision-making process
	Incident response	To facilitate their understanding of incident mitigation, response, and remediation.
(Furnell, 2021)	Information security governance	To facilitate governance and compliance
	Business resilience	Basic business resilience skills can enhance anticipation, action, and defensive strength.
	Compliance	To facilitate understanding of the relevant acts, regulations, and compliance frameworks.
(Almeida, 2025)	Risk management, organizational factors, and governance	To facilitate their cyber risk management decision-making process

4. Discussion

The research question of this study focuses on identifying the cybersecurity competencies critical to the TMT's strategic cybersecurity management in critical infrastructure organizations. However, the literature on such competencies is very limited. Most studies examine the competencies of cybersecurity experts within the TMT, with particular attention given to roles such as CIO, CISO, and CTO (Anderson, Ahmad and Chang, 2022, 2024b). While the TMT comprises senior management, its functional diversity poses challenges to collaboration (Lorenz and Buchwald, 2023). Consequently, the role of CISO as a technical professional within the team may create functional diversity issues that affect overall decision-making processes (Ashenden and Sasse, 2013).

Our results indicate that board-level IT competencies have received some attention from researchers (Benaroch and Chernobai, 2017; Benaroch and Fink, 2021; Jewer and McKay, 2025) Though their core cybersecurity management competencies remain under-researched. The results indicate that many studies recognize the critical importance of the cybersecurity strategic responsibilities for top management of critical infrastructure organizations. However, most emphasize the competencies and skills of the technical members of the TMT, such as CISO, CIO, CTO, and CDO (Ashenden and Sasse, 2013; Onibere, Ahmad and Maynard, 2017; Kappelman *et al.*, 2019; Bendig *et al.*, 2022; RenÃ, 2022; Lorenz and Buchwald, 2023; Ramezan, 2025). Furthermore, the review suggests that emphasis is often placed on specific TMT members regarding cybersecurity competencies, without acknowledging that all team members share responsibility for organizational cybersecurity governance, resilience, and compliance. Additionally, our review noted discrepancies about the composition of the TMT. While this study does not aim to define team composition, it highlights the strong need for all TMT members to be cybersecurity-proficient and acquire a certain level of cybersecurity management competencies to support strategic cybersecurity management responsibilities and to aid in collective mindfulness (Järveläinen *et al.*, 2025). This is very important in critical infrastructure, where information technology and operational technology are a mix. Finally, we observed that only communication skills, incident response, and risk management are considered, and only for cybersecurity leaders (Anderson et al., 2022, 2024). Information security governance, information security strategy, and information risk management were also identified Furnell, (2021).

5. Conclusion

This study sets out to answer the research question: which cybersecurity management competencies have been identified as supporting TMT strategic responsibilities for cybersecurity management in CI? Despite the strategic importance of cybersecurity management in this sector, our results reveal very limited research addressing the cybersecurity management competencies of the TMT. Most studies focus on the competencies of technical roles, such as CIO, CISO, or CTO, neglecting the overall competencies of all members.

Our review found that although TMT composition, size, and skills vary depending on the size of the organization, it is consistently evident that TMT is primarily responsible for the strategic decisions related to cybersecurity.

The results revealed five main themes that are crucial for critical infrastructure organizational cybersecurity management processes: leadership, organization, cybersecurity, learning, and competence. This supports the identification of competencies essential to TMT's strategic responsibilities. Finally, identifying cybersecurity management competencies will support the enhancement of cybersecurity as the protector of the organizational value creation capabilities of CI. This review also represents a step toward creating a cybersecurity framework tailored to TMT's strategic cybersecurity management responsibilities.

5.1 Limitations and Future Research

This study is limited to some journals. We chose to systematically study a limited sample of high-quality outlets, but future research could identify additional central competencies through a broader search. This review can extend into an empirical study that applies the identified competencies and assesses the extent of TMT's level of cybersecurity management competencies in different types of organizations.

Ethic Declaration: I declare that ethical clearance was not required for this research

AI Declaration: I declare that AI was not used in the creation of the paper; however, Copilot and Grammarly were used for grammar and proofreading.

Abstract: Closed-circuit television (CCTV) systems generate huge amounts of video material, making manual inspection slow, inefficient, and prone to missing evidence. As surveillance scenarios grow more complex, investigators require automated tools capable of understanding extensive, unstructured recordings and supporting natural-language search, which most existing systems cannot provide. Current video-analysis systems usually focus on isolated tasks such as detection, action recognition, or captioning, producing fragmented outputs that lack the consistency and explainability needed for forensic work. This research presents MAGNAS, an intelligent CCTV retrieval platform that converts raw footage into a searchable metadata index using a multi-phase pipeline integrating person detection, multi-object tracking, visual attribute extraction, and action recognition. It generates structured representations including bounding boxes, timestamps, appearance attributes, and actions stored in an SQLite database. Users describe people or events via a natural-language interface, and the system translates these into structured filters for accurate set-theoretic retrieval. MAGNAS was evaluated using mAP for detection, Recall@K and Precision@K for retrieval, and temporal IoU for action alignment. Results show strong person-detection performance and high retrieval accuracy, especially for queries with multiple appearance attributes. Attribute extraction was largely precise, despite challenges with delayed VLM processing, inconsistent action detection under difficult camera angles, and limited temporal accuracy (tIoU = 0.2649). Overall, MAGNAS significantly reduces search time and improves identification of people of interest in large-scale CCTV archives, highlighting the value of organized, explainable video indexing for future investigative technologies and law enforcement applications.

Keywords: CCTV, Video retrieval, Natural language processing, Computer vision, Digital forensics

1. Introduction

The CCTV systems have evolved into one of the most prolifically used security technologies, and video surveillance has been implemented in airports, banks, retail spaces, and smart cities and brings about rapidly growing amounts of unstructured footage as the number of cameras in the world has exceeded a billion by 2021 (Subha et al., 2023). This information is useful to prevent crime, rebuild the events, and assist investigations, and human operators can only observe a few screens and their performance drops in case of fatigue, which is why manual inspection is inconsistent and inefficient as stated by Subha et al. (2023). Artificial intelligence and computer vision studies have thus prioritized the automation of video interpretation with models like YOLO to detect objects and CNN/RNN to recognize behaviors, and video-to-text systems based on natural language search, as Khurana and Deshpande (2021) explain. Initial techniques based on background subtraction, semantic tagging, and motion detection developed into semantic indexing and multimodal systems such as TagBook that showed that it was possible to unsupervisedly characterize events, as stated by Mazloom et al. (2016). Recent developments now involve VLAB (He et al., 2025) and PRVR (Dong et al., 2022), which have been trained to better the video-language association, but most of them are evaluated on controlled data sets and have issues related to low-resolution, occlusion, and low-light conditions found in real CCTV images, as pointed out by Wan et al. (2021). Although technologies have made progress, existing systems tend to focus on single functions like anomaly detection, captioning, or retrieval without providing solutions that can be used in the real-world surveillance setting that can be scalable, which is why improved unified solutions are required.

The fast growth of CCTV systems has led to huge amounts of unstructured video that need to be brought to bear on intelligent actionable information as highlighted by Subha et al. (2023) but current manual reviewing systems are not keeping up with the volume and complexity. Other forms of early indexing and tagging techniques enhanced organization but were limited to low-level features enabling low scalability like Saravanan (2016) and TagBook by Mazloom et al. (2016), multimodal hypergraph retrieval by Li et al. (2024), and hierarchical graph search models by Song et al. (2022) enhanced the semantic alignment of video and text. The minimal effect of NLP-based technologies such as video captioning by Wu et al. (2024), multi-sentence summarization by Masoomeh Nabati and Alireza Behrad (2020), and Video-QA by Khurana and Deshpande (2021) have also helped reduce the semantic gap, although their results are still underwhelming on continuous CCTV footage, where the computational cost, data capacity, and inefficiency become critical issues. Although supervised contrastive

learning and multimodal captioning models have enhanced robustness and similar accuracy, according to Hirata et al. (2021) and Wu et al. (2024), real CCTV conditions of low light, blur, occlusion, and varying dynamics of a scene still remain a problem to model reliability, an issue brought up by Wan et al. (2021) and Li et al. (2024). The existing literature is currently divided with anomaly detecting, captioning and retrieving being studied separately without any combination of identification, indexing, and video-to-text translation into a single, scalable system that guarantees the timely and efficient CCTV processing, which is why the system that would help alleviate these limitations and provide the means of timely efficacious CCTV processing is necessary. Three major research questions will guide the study:

RQ1: What approaches can combine multiple pretrained models to generate descriptive representations of CCTV footage that support faster and more intuitive search?

RQ2: What methods enable a single, unified query to retrieve relevant moments from long CCTV recordings based on actions, objects, or events?

RQ3: How can CCTV footage be transformed into structured outputs such as timelines, labels, or event summaries that allow investigators to navigate videos more efficiently?

The primary aim of this project is to develop a unified CCTV retrieval system capable of single-query natural-language search, enabling investigators to rapidly locate individuals, actions, and events across extensive surveillance footage by converting visual content into structured metadata and reducing reliance on lengthy manual review. To achieve this aim, the system integrates multiple pretrained models that detect objects, actions, and relevant visual cues in CCTV video, transforms these outputs into searchable representations such as labels, timestamps, and contextual descriptions, and implements a complete end-to-end pipeline that unifies detection, indexing, and retrieval into one efficient platform. Overall, the objective is to enhance investigative workflows by shortening video-analysis time, improving the accuracy and explainability of retrieval results, and providing a scalable metadata-driven solution suitable for real-world forensic and security applications.

2. Problem Background

Early video indexing relied on low-level features with limited scalability (Saravanan, 2016). TagBook introduced unsupervised semantic characterization (Mazloom et al., 2016), while multimodal approaches like hypergraph retrieval (Li et al., 2024) and hierarchical graph models (Song et al., 2022) improved video-text alignment. Video captioning systems (Wu et al., 2024; Nabati & Behrad, 2020) and Video-QA frameworks (Khurana & Deshpande, 2021) reduced the semantic gap but underperform on continuous CCTV. Recent models like VLAB (He et al., 2025) and PRVR (Dong et al., 2022) enhance video-language pretraining, yet real-world conditions—occlusion, low light, blur—remain problematic (Wan et al., 2021). Supervised contrastive learning (Hirata et al., 2021) improves robustness, but no existing system fully integrates detection, tracking, attribute extraction, action recognition, and natural-language search into one scalable forensic platform suitable for real CCTV conditions.

3. Methodology

The three-phase approach is used in this project. At the initial stage, a set of pretrained models were experimented on sample CCTV video to find out which models could be reliably used to assist in detection, attribute extraction and action recognition in the environment of real surveillance. During the second phase, the chosen components have been integrated into an entire platform with user interface, Flask backend, and a five-step automated pipeline that takes uploaded videos and allows search through natural languages. During the last stage, the system was tested with the help of the new CCTV videos in order to measure the accuracy of retrieval, the speed of the response, and the overall stability of the system in the conditions of the real investigation.

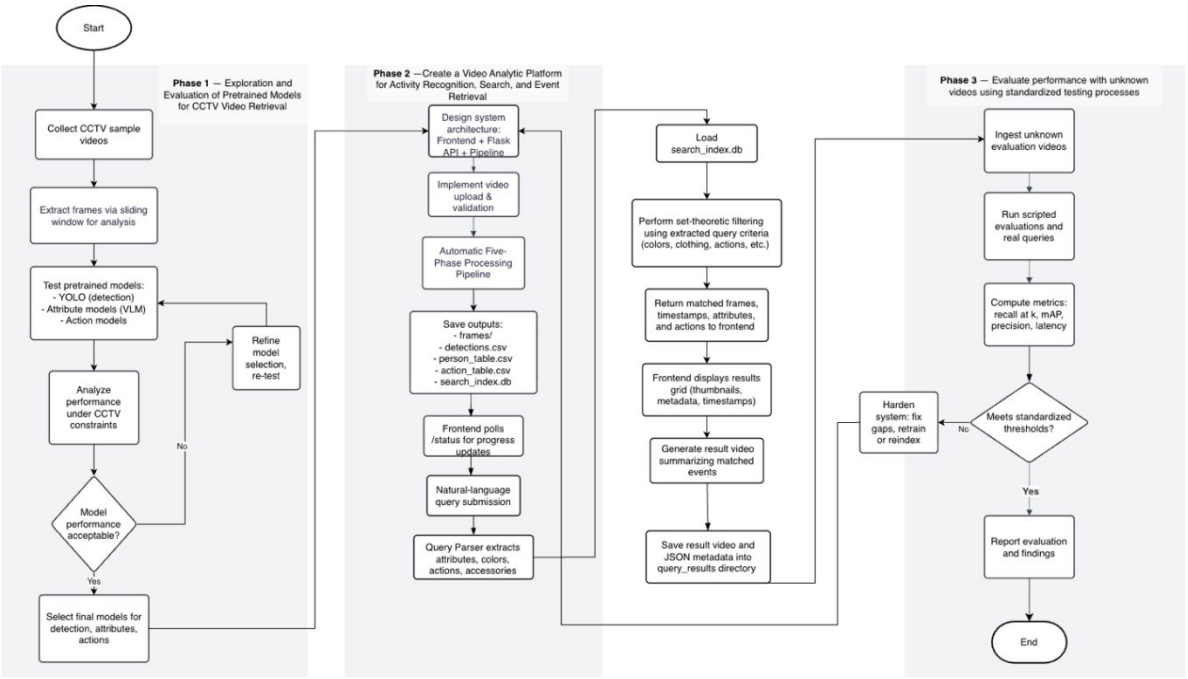

Figure 1: Operational Framework of the Study

3.1 Phase 1: Exploration and Evaluation of Pretrained Models for CCTV Video Retrieval

Phase 1 set MAGNAS baseline with a large variety of pretrained models, reviewed, and experimentally tested to be able to detect objects, extract attributes, recognize actions, track objects, and align texts with images. Due to the low resolution of CCTV footage, compressed artifacts, blur, poor illumination, occlusion, and low effective frame rate, this stage aimed at identifying models that would execute in the most favorable conditions when subjected to real surveillance. The analysis focused on the stability of detecting, the consistency of detecting over time, resistance to blur, fidelity of clothing colors and generalization to real recordings.

3.1.1 Review of pretrained models evaluated

Some models were experimented in terms of their functions in the analysis chain. In order to look at object-detection and tracking, YOLOv8 (m, l, x), YOLOv10, YOLO11, and RT-DETR were evaluated. YOLOv8m and YOLOv8x using ByteTrack were shown to be much more successful on degraded CCTV clips, particularly in low-light, compressed, and crowded scenes, and provides good small-person detection and dependable track IDs with minimal costly ReID modules.

Action recognition models such as SlowFast, TimeSformer, VideoMAE (base and large), MViTv2, Uniformer and InternVideo2 have also been tested. Most of the models performed poorly on noisy CCTV clips, and low FPS, though they were strong in Kinetics. VideoMAE-large was chosen due to its 16 frames input and powerful temporal representation and a custom HMDB51-finetuned checkpoint achieved much better surveillance-action performance than Kinetics-only pretrained models.

Person-attribute classifiers included SOLIDER, PromptPAR and OpenPAR, which were found to have an issue with poor crops, changes in lighting and compression noise. Then, vision-language models were tested based on zero-shot and instruction-tuning (CLIP, BLIP-2, LLaVA-1.5, Qwen-VL, Qwen2-VL, Qwen3-VL). Qwen3-VL-2B-Instruct that was deployed locally and quantized provided the highest accuracy, high-blur image, and structured outputs, particularly when the prompts contained context of the detected objects.

3.1.2 Experimental findings

Key insights were made in phase 1 experiments. Action models trained on Kinetics tended to get similar movements confused e.g. walking vs. running, when squeezed and at low frame rates. VideoMAE-large finetuning on HMDB51 enhanced significantly the recognition of surveillance-defensive actions, including walk, run, wave, pick, throw, punch, kick, smoke, drink, and clap. Dedicated attribute classifiers could not process blurred or low-resolution person crops and vision-language models, particularly Qwen3-VL-2B-Instruct with contextual hints, such as person holding a phone, were far more accurate on held objects, accessories, and

clothing. The results of YOLOv8 with Byte Track provided the most consistent person track across lighting variations and occlusion, and removed individual ReID models. Quantized Qwen3-VL-2B-Instruct deployed locally was able to operate offline with a tolerable latency of approximately 1.5 to 2 seconds per person crop and was therefore feasible in practice. These outcomes noted the most consistent factors during the noise of CCTV and informed the final MAGNAS architecture.

3.1.3 Final adopted model and pipeline

Phase 1 was successful as it ended with a strong and an effective model setup. YOLOv8m and YOLOv8x were used in object detection with low-resolution, compressed, low-light CCTV and in tracking with the assistance of Byte Track since they possess high ID continuity without ReID. Qwen3-VL-2B-Instruct utilized the attributes of people based on the context of the items that were detected by YOLO to enhance recognition of objects and clothes. VideoMAE-large finetuned on HMDB51 provided action classification achieving 83% validation accuracy on surveillance-style actions. This combination formed the foundation for Phase 2 integration.

3.2 Phase 2: System Implementation and Integration

3.2.1 Operational architecture and ingestion workflow

MAGNAS is based on the modular system with interface, backend, pipeline, and storage to transform raw CCTV video into searchable metadata. The MagnasFinal.html interface allows the investigator to upload the footage, monitor the progress, and search by natural language, and the Flask backend allows managing authentication, uploads, pipeline execution, and logging. Each video is processed by a five-stage background pipeline, the first stage of which is to extract frame, followed by detecting and tracking people with the help of YOLO, attribute generations with a vision-language model, short term action recognition and, finally, all data are summarized into a SQLite search index. All the intermediate and final output are stored in the table directory so that they can be easily accessed.

3.2.2 Query processing, search logic, and retrieval mechanism

After the ingestion pipeline completes and search_index.db is created, the natural-language queries can then be typed in by the investigators through the interface. Once queries are typed in A query such as: a man in a dark green hoodie with a backpack walking will be logged in the magnas_activity.log and the query parser used to process it in the system. The parser acquires formal search attributes such as colors, types, accessories, gender and actions of clothes. MAGNAS retrieves the results according to set-theoretic metadata filtering of metadata in search_index.db. The backend loads detections.csv, person_table.csv and action_table.csv, and finds all the entries that meet all the requirements and counts their intersection. This provides results to the investigation that are deterministic, explainable and reliable. Organized information that is sent by the backend includes frame numbers, timestamps, bounding boxes, attributes of persons, and inferred actions. Each individual can view the findings in frame thumbnails on the front-end. Bounding boxes on an MP4 video are created on command by generating a summarized video file using create_result_video.py and stored in the query results directory.

3.3 Phase 3: Evaluate the Performance of the Platform Using Unknown Videos Based on Standardized Testing Processes

The main aim of Phase 3 is to thoroughly test the platform's reliability, scalability, and accuracy by using originally unseen CCTV video. This guarantees that the created platform applies beyond the training environment and works well in real-world surveillance scenarios. The study uses established evaluation practices to assess algorithmic correctness, system responsiveness, and user experience while maintaining forensic transparency and security.

3.3.1 Evaluation metrics

On the platform, standardized retrieval metrics are computed after testing. Recall@K and Precision@K are used to determine the performance of the top-K relevant clips (Radlinski and Craswell, 2010). Mean Average Precision (MAP) measures the ranking quality across queries (Bellogín et al., 2017). Temporal accuracy of localized events is assessed by temporal IoU and mean Temporal Average Precision (mTAP) (Gao et al., 2017). Query latency (P50/P95) and indexing throughput measure responsiveness and scalability (Mackenzie et al., 2017).

4. Results and Analysis

In this section, MAGNAS performance will be of all components including interface, processing, retrieval accuracy, temporal localization, and overall functionality, in which quantitative and qualitative results are presented.

4.1 Ingestion and Indexing Results

The ingestion pipeline consists of five primary steps, each of which is designed to enable high-quality information extraction and reliable indexing. The system extracts timestamped frames at 3 frames per second (adjustable), balancing temporal precision with storage and processing performance. YOLOv8 is put to use for accurate person recognition, followed by Byte Track for reliable identity tracking. For each identified individual, the system saves a narrow crop for attribute and action analysis and a context crop with 150 px padding, which proved useful for catching surrounding objects and hand-held items that frequently fall outside tight bounding boxes. Each crop is processed using a locally hosted Qwen3-VL-2B model, which extracts precise human characteristics. VideoMAE-Large is implemented with movable temporal windows and post-processing smoothing achieving 83% accuracy. All Metadata has been compiled and saved in search_index.db for faster retrieval using combination indexing (frame, track_id) and better attribute-action fusion.

4.2 Quantitative Evaluation

4.2.1 Retrieval accuracy metrics (Recall@K, Precision@K, mAP)

The retrieval-stage evaluation demonstrates that the system achieves strong ranking and retrieval quality across diverse query types. The overall Mean Average Precision (mAP) reached 0.9597, indicating excellent ranking consistency and the system's ability to place relevant clips at higher positions. Recall@K: Recall@1 = 0.4450 (44.5%), Recall@5 = 0.9800 (98.0%), Recall@10 = 1.0000 (100%), Recall@20 = 1.0000 (100%), Average Recall = 0.8563 (85.63%). Figure 2 shows Recall@K results showing the system's ability to retrieve relevant clips within the top-K returned items. High Recall@5/10/20 demonstrates strong retrieval coverage.

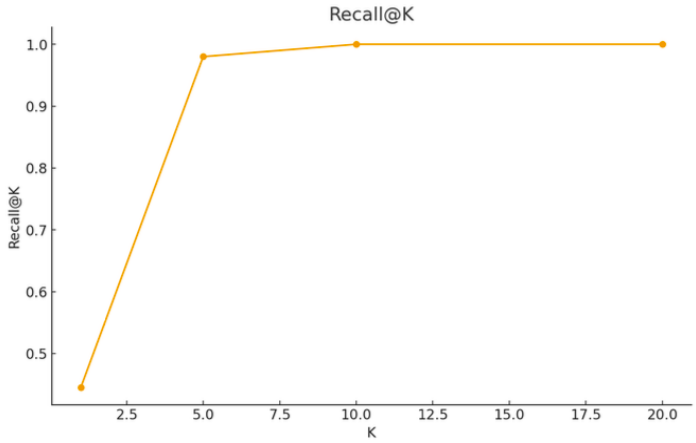

Figure 2: Recall@K results showing strong retrieval coverage

Precision@K: Precision@1 = 0.9000 (90%), Precision@5 = 0.5200 (52%), Precision@10 = 0.2700 (27%), Precision@20 = 0.1350 (13.5%), Average Precision = 0.4563 (45.63%). Precision@1 remains high, gradually decreasing as K increases. Per-Query AP Performance: Hijab/headscarf: AP = 1.0, Walking/stairs: AP = 1.0, Shaking hands: AP = 1.0, Green jacket: AP = 1.0, Group standing/talking: AP = 0.8875, Baseball swing: AP = 1.0, Riding horse: AP = 1.0, Helmet/hat: AP = 0.71, Jumping/diving: AP = 1.0, Wearing glasses: AP = 1.0. Overall, the system exhibits excellent retrieval accuracy. High mAP and Recall@5/10/20 values show that relevant clips are consistently retrieved. Precision decreases at larger K values, as expected in ranked retrieval systems.

4.2.2 Temporal localization (Temporal IoU and mTAP)

Temporal localization evaluates how accurately the system identifies the start and end boundaries of actions. Overall performance shows partial overlap with ground truth. Overall Metrics: Average Temporal IoU = 0.2649, Overall mTAP = 0.2391. mTAP Across IoU Thresholds: mTAP@0.3 = 0.2859, mTAP@0.5 = 0.2859, mTAP@0.7 = 0.1455.

Per-Video Performance: 4PEOPLE: Avg tIoU = 0.2327, mTAP = 0.1570; Riding: Avg tIoU = 1.0000, mTAP = 1.0000; Baseball: Avg tIoU = 0.3185, mTAP = 1.0000; Green Jacket: Avg tIoU = 0.2857, mTAP = 0.4545; Hijab: Avg tIoU = 0.3183, mTAP = 0.3788; Running: Avg tIoU = 0.1182, mTAP = 0.2020; Shakehand: Avg tIoU = 0.2926, mTAP = 0.3636. Figure 3 shows Average Temporal IoU (tIoU) per video. Simple, continuous actions such as Riding show perfect boundary alignment, while multi-person or fast-motion actions result in lower tIoU.

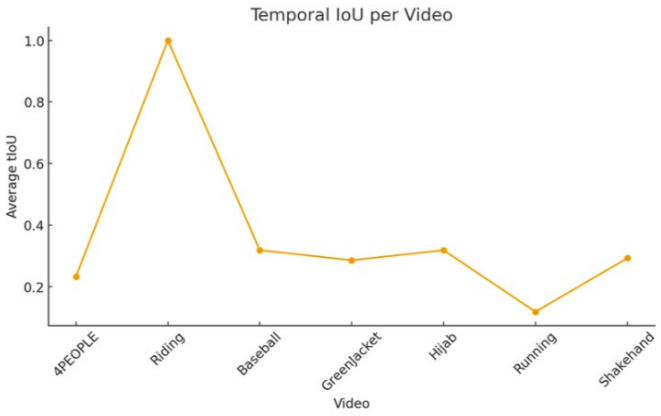

Figure 3: Average Temporal IoU per video

The system performs well on simple, continuous actions such as riding and baseball. Performance decreases in multi-person scenes, fast transitions, subtle actions, and scenes with occlusion.

4.2.3 System performance metrics

System performance was evaluated across all seven videos, each processed through the full pipeline. Overall Throughput: 100% pipeline completion, Total processing time: 659.25 seconds, Average processing time per video: 94.18 seconds, Fastest video: 39.79 seconds; slowest: 233.73 seconds, Average speed: 5.21 FPS (0.20× real-time). Hardware Utilization: GPU: NVIDIA GeForce 4090, Average GPU memory: 5.45 GB, Peak GPU memory: 14.6 GB, RAM usage: ~73 MB (GPU-bound workload). Phase-Level Breakdown: Phase 3 (VLM Attributes): Slowest step—avg 56.76 s, peak 174.43 s; Phase 4 (Action Inference): Avg 26.47 s; Phase 2 (YOLO Detection): Avg ~7 s; Phases 1 & 5 (Extraction and Indexing): Fastest—avg ~3 s each. The pipeline is stable and predictable, with no failures. The system is slower than real-time due to the combination of YOLO, VLM, and VideoMAE models, but memory usage remains stable and efficient.

4.3 Qualitative Evaluation

The qualitative results show significant improvements in retrieval accuracy, user experience, and platform stability. The system now correctly returns the subject's continuous track, even with complicated multi-attribute descriptions. Specific instances include: "man in black jacket walking," "woman in pink top with backpack," "person riding bike carrying bag." The incorporation of context crops eliminated previous failures when important things, such as cups, phones, or bags, went outside the tight crop. This guarantees that all necessary attributes and moved items have been recorded.

The natural language query engine also worked effectively. Attribute and action names were accurately translated to metadata fields, including: "riding" → mapped to action ride_bike; "girl", "woman", "female" → reliably classified as female; "cap", "hat", "beanie" → matched via the accessories field; "carrying cup", "holding mug", "with bottle" → identified via objects_held.

All major issues documented in earlier versions of the system were fully resolved: No more incorrect person retrieval due to the new (frame, track_id) intersection method; No more corrupted CSV files after implementing strict response cleaning for VLM outputs; Gender detection no longer defaults to male owing to improved attribute parsing; Hand-held object detection is now consistently captured through context crops; Action verb mismatches were eliminated using refined language-to-action mapping rules. These enhancements increase system stability, confirm module robustness, and prepare the platform for real-world forensic deployments.

This section demonstrated that MAGNAS is a reliable complete CCTV search platform, completing all processing steps and generating consistent retrieval results. The results revealed great retrieval accuracy, consistent person-level tracking, and predictable system performance. While temporal localization and attribute extraction

remain difficult in complicated scenarios, the overall assessment shows that the system is effective, useful, and in line with the project's goals.

5. Discussion

The results of this research created MAGNAS, an extensive surveillance-video retrieval system that includes frame extraction, detection, attribute identification, action categorization, and natural-language search. The results reveal that the system performs well in retrieval accuracy, with a high mAP and outstanding Recall@K, making it suitable for person-based forensic searches. The system's interface and logging features also ensured that pipeline execution was reliable, information was generated consistently, and it was useful. Temporal localization was worse, although it performed well for obvious, long-duration activities.

Future work can improve MAGNAS' accuracy, scalability, and real-world application. One significant objective is to improve identity consistency by incorporating a dedicated person Re-Identification (ReID) 51model, which would decrease ID switches and allow the system to track persons more reliably over longer sequences. Furthermore, more complex temporal action models, such as VideoMAEv2, SlowFast, or TimeSformer, might be used to give clearer action boundaries and improved identification of subtle or slow-movement behaviors. Extending the dataset is also important. Evaluating the system on large-scale, diversified CCTV material containing nighttime recordings, busy locations, occlusions, low-resolution cameras, and different views would considerably improve generalization. Synthetic data augmentation and controlled data generation could help expose the system to rare or difficult conditions. The platform's forensic use might potentially be increased by incorporating new analytical modules such as posture estimation, vehicle identification, interaction analysis (e.g.," person passing an object"), or anomaly detection. More intuitive user features, such as visual timelines, heatmaps of identified activities, and multi-query filtering, would make the platform more user-friendly for investigators. Finally, performance optimization by model reduction, batching, or TensorRT acceleration may minimize processing time, bringing it closer to real-time operation. Distributed or cloud-based deployments may also enable the system to manage higher amounts of video data.

6. Future Work and Conclusion

6.1 Future Works

The accuracy, scalability, and applicability of MAGNAS can be improved in the future. The ID switches and long sequence tracking could be better by adding a dedicated person Re-Identification model. More sophisticated temporal action models, including VideoMAEv2, SlowFast, or TimeSformer, might offer better action boundaries and identify smaller-scale actions. Generalization would be enhanced by extending the evaluation datasets with various CCTV footage at night, in overcrowded areas, with occlusions, low resolution, and different viewpoints. Synthetic data augmentation may expose the system to uncommon conditions. Additional modules for forensic use can include posture estimation, vehicle identification, interaction analysis, or anomaly detection. Visual timelines, multi-query filtering, and activity heatmaps can improve user experience. Optimization through model reduction, batching, or TensorRT acceleration may reduce processing time toward real-time operation. Larger video volumes could be managed via distributed or cloud deployment.

6.2 Conclusion

MAGNAS has successfully delivered a functioning, end-to-end CCTV search engine capable of quick and accurate retrieval across a wide variety of queries. While there are still limits in temporal accuracy and in demanding visual situations, the system shows great promise for practical forensic applications with continued development and broader dataset review. MAGNAS has the potential to become a strong real-world investigative tool.

Ethics Declaration: This study did not require ethical approval because no human or animal subjects were involved. The authors affirm that no human research participants were involved in this study; hence, it is not applicable.

AI Declaration: The Authors declare that AI was not used to write the manuscript and that the content represents the authors' original writing, except where an AI tool was used to edit the manuscript to enhance clarity.

A Harmonised Dashboard for Smart Home Device Security

Samiah Alghamdi, Steven Furnell and Steven Bagley
University of Nottingham, UK

Samiah.alghamdi@nottingham.ac.uk
Steven.Furnell@nottingham.ac.uk
Steven.Bagley@nottingham.ac.uk

Abstract: Smart homes increasingly rely on Internet-connected devices, offering convenient services yet raising significant concerns regarding the protection of personal information. As the number and variety of devices continue to grow, users face fragmented and inconsistent security, privacy, and data-management controls across different manufacturer ecosystems. Although commercial smart home applications provide centralised access, their interfaces often lack coherent structures for managing essential protection features, making it difficult for users to locate controls, understand device status, and maintain awareness of how personal data is collected, stored, and shared. This paper presents the design and evaluation of a harmonised approach to simplify and unify the user experience, via an integrated security and privacy dashboard. The dashboard provides a unified interface for managing heterogeneous smart home devices, with core functionalities structured around Security, Privacy, and Data Management to support consistent navigation and user control. A task-based study with 16 smart-home users evaluated the dashboard against Google Home, Amazon Alexa, and Apple HomeKit applications. Participants completed scenarios involving software updates, microphone controls, reviewing and deleting voice-assistant recordings, checking camera footage, and managing location services. Performance was assessed using task completion rates, task completion time, number of clicks per task, and the System Usability Scale (SUS), alongside qualitative feedback from participants. Results showed that participants were able to complete every task using the dashboard, whereas completion rates on commercial applications were substantially lower. Tasks were completed more quickly and in fewer steps, and the dashboard achieved an "excellent" rating on the System Usability Scale. Qualitative feedback highlighted its intuitive navigation, unified structure, and clear organisation of device-related information. Overall, the findings demonstrate that a harmonised dashboard can reduce complexity, improve user control, and support informed decision-making within smart home environments, ultimately enhancing trust and security for everyday users.

Keywords: Internet of Things, Smart home, Security, Privacy, Usability

1. Introduction

Smart devices have become an integral part of everyday life, with a growing number of households adopting smart home technologies to improve convenience, efficiency, and automation. These environments typically consist of multiple interconnected Internet of Things (IoT) devices that communicate through home networks and cloud services. While such technologies provide significant benefits, they also introduce serious security and privacy challenges that are often not apparent to non-technical users.

Recent studies indicate that managing security and privacy in smart homes has become increasingly challenging due to the rapid growth and heterogeneity of interconnected IoT devices from multiple manufacturers, which rely on diverse protocols, platforms, and continuous Internet connectivity. This complex architecture often results in fragmented ecosystems, inconsistent device interactions, and unclear information presentation, making effective management difficult for end users and leading to misconfigurations and security vulnerabilities (Ahmed and Ko, 2016; Zhu et al., 2023; Vardakis et al., 2024; Magara and Zhou, 2024).

Studies have highlighted the seriousness of these issues, demonstrating that a large proportion of consumer smart devices remain vulnerable to known security threats and that sensitive data transmissions can be exposed to interception (Zhu et al., 2023). These findings emphasise the widespread vulnerabilities in smart home environments and the urgent need for enhanced, user-oriented security solutions. Moreover, integrating smart home systems with cloud services, artificial intelligence, and mobile applications introduces additional security complexities. As digital ecosystems extend beyond local networks, it is more difficult to define and maintain secure boundaries. Cyber attackers can exploit weak configurations and unencrypted communication channels to intercept sensitive information or gain unauthorised access (Ahmed and Ko, 2016; Kalbo et al., 2020).

As responsibility for managing smart home systems increasingly shifts to end users, many individuals are required to configure, monitor, and maintain the security and privacy of their connected devices without sufficient technical knowledge. Previous studies highlight that users frequently struggle to understand device configurations, data flows, and privacy implications, resulting in misconfigurations and exposure to potential cyber threats (Ahmed and Ko, 2016; Geneiatakis et al., 2017).

Although many commercial smart home applications provide centralised access to devices, their interfaces primarily focus on convenience and automation rather than on user-centred security and privacy management. Security mechanisms frequently operate invisibly in the background, and privacy controls are often buried within complex menus or distributed across multiple applications. Consequently, users tend to rely on default configurations or implicit trust in manufacturers rather than actively managing their smart home security and privacy (Shuhaiber and Mashal, 2019).

This paper addresses these challenges by focusing the design and evaluation of a user-centred interactive dashboard, explicit designed to reduce complexity, improve user control, and support informed decision-making in smart home environments. By consolidating security and privacy information from multiple devices into a single interface, the approach aims to enhance user understanding, trust, and overall smart home security.

The remainder of this paper is structured as follows. Section 2 reviews security and privacy challenges in smart home environments and discusses related vulnerabilities and existing research in this area. Section 3 presents the design of the proposed harmonised security and privacy dashboard. Section 4 describes the user evaluation methodology and reports the experimental results. Finally, Section 5 concludes the paper.

2. Security and Privacy in Smart Homes

A smart home refers to a residential environment where household devices and systems are connected to the Internet, enabling automation, remote monitoring, and intelligent control through smartphones or voice-based interfaces (Satpathy, 2006). These environments integrate heterogeneous devices communicating via technologies such as Wi-Fi, Bluetooth, and ZigBee, and often rely on cloud-based services for data processing and coordination. While such connectivity enables convenience and automation, it also introduces security and privacy risks due to the continuous exchange of data and remote access.

2.1 Security and Privacy Vulnerabilities in Smart Home Devices

Recent systematic reviews have further confirmed that smart home IoT environments remain vulnerable to multiple security threats, including unauthorised access, insecure communication channels, and weak authentication mechanisms (Ben-Nakhi, 2025; Popoola et al., 2024). Numerous vulnerabilities have been identified in IoT devices. Eavesdropping, for instance, occurs when an attacker intercepts data transmitted between devices (Mohammad et al., 2019). Moreover, IoT devices are susceptible to various attacks, such as sleep deprivation, node capture, and replay attacks (Lu and Xu, 2018). Devices remain vulnerable due to continuous Internet connectivity and automated configuration mechanisms, which often retain manufacturers' default security settings.

Several studies have documented concrete security and privacy vulnerabilities in consumer smart home devices. Smart speakers have been reported to suffer from several security and privacy vulnerabilities, including continuous listening, unauthorised recording, and weak speech authentication mechanisms (Jackson and Orebaugh, 2018). Research on adversarial voice attacks has further demonstrated that attackers can inject inaudible commands without the user's knowledge, enabling covert device manipulation (Carlini et al., 2016; Zhang et al., 2017). Similar concerns have been identified in smart cameras and video doorbells. Prior work shows that weak authentication, insecure configuration management, and exposed network services can lead to the leakage of sensitive audio and video data (Bugeja et al., 2018).

Beyond vulnerabilities in individual devices, security and privacy risks also emerge at the ecosystem level. Studies have shown that many IoT applications are overprivileged, granting excessive permissions that unnecessarily expand the attack surface (Fernandes et al., 2017). Additionally, insecure over-the-air firmware update mechanisms and voice-based interfaces introduce further attack vectors, enabling hackers to manipulate device behaviour or inject malicious commands (Meng et al., 2018).

2.2 Privacy Concerns in Smart Homes

Privacy in smart home environments refers to users' ability to understand and control how personal data is collected, processed, and shared by connected devices and services (Kotz et al., 2009). Unlike traditional computing environments, smart homes operate through continuous data collection, capturing fine-grained information about users' behaviours, routines, and interactions within private living spaces.

Prior research has shown that privacy risks extend beyond direct data disclosure. Even encrypted or metadata-only network traffic can be analysed to infer sensitive information, including occupancy patterns, daily routines,

and individual activities (Apthorpe et al., 2017). As a result, privacy threats in smart home environments often arise through indirect behavioural inference rather than explicit data breaches.

In addition to these technical risks, recent studies highlight that users remain concerned about how personal data collected by smart home devices is stored, processed, and shared with third parties (Magara and Zhou, 2024; Haney et al., 2025).

Although numerous technical solutions for privacy protection have been proposed, human–computer interaction studies consistently demonstrate that users struggle to understand data flows and privacy implications in smart home ecosystems. Users frequently prioritise convenience over privacy, rely on default configurations, and lack awareness of how their data is collected and used (Emami-Naeini et al., 2019). This gap highlights a mismatch between existing privacy mechanisms and users' practical ability to manage them effectively.

2.3 Related Work and Existing Solutions

Existing research on smart home security and privacy has examined both backend enforcement mechanisms and user-facing tools. Backend-oriented solutions, such as ProvThings (Wang et al., 2018) and SmartAuth (Tian et al., 2017), focus on detecting malicious behaviour and misconfigurations within IoT ecosystems. While these approaches are effective at a technical level, they are primarily designed for developers and system administrators, offering limited visibility or control for end users.

More recent work has shifted attention toward user-facing interfaces, introducing interactive dashboards to improve user awareness of device activity and data sharing. Systems such as SaferHome (Windl et al., 2022) and Peekaboo (Jin et al., 2022) visualise aspects of smart home behaviour, helping users understand where and how data is processed and transmitted. However, these solutions typically address specific dimensions of security or privacy and do not support unified management across heterogeneous devices.

Commercial platforms, including Google Home, Amazon Alexa, and Apple HomeKit, provide centralised device control but operate within closed ecosystems. As a result, they offer limited transparency into permissions, data flows, and security configurations. Users are often required to manage security and privacy settings across multiple fragmented interfaces, which increases cognitive load and raises the risk of misconfiguration (Geneiatakis et al., 2017).

In addition to commercial platforms, several open-source smart home frameworks have been developed, such as Home Assistant (Home Assistant, 2024) and OpenHAB (OpenHAB, 2024) provide robust interfaces that facilitate the monitoring of household devices and tracking energy generation and consumption through their integrated Energy Dashboards. However, their interfaces primarily focus on automation and device control rather than structured security and privacy management, which can make it difficult for non-technical users to understand and manage protection settings effectively.

Overall, prior work demonstrates significant progress in addressing smart home security and privacy challenges. Nevertheless, existing solutions remain fragmented, frequently separating security from privacy and prioritising backend protection over user-centred interaction. This gap highlights the need for unified and accessible interfaces that better support user awareness, understanding, and effective security and privacy management across diverse smart home devices.

3. Designing a Harmonised Security and Privacy Dashboard

The proposed dashboard is designed to address the fragmentation and complexity of security, privacy, and data management in current smart home environments. To achieve this, an effective all-in-one smart home solution should integrate key capabilities, including improved visibility of device status, integrated management of security and privacy settings, and greater transparency in data management.

The design requirements for the proposed dashboard were informed by prior analysis conducted by the authors (Alghamdi et al., 2024), alongside established usability and human–computer interaction principles. These insights were used to identify key usability challenges and user needs in smart home environments.

Based on these insights, the design of the proposed dashboard is guided by the following requirements:

- **Unified Interface**: Provide a dashboard to manage security, privacy, and data across all devices.
- **Consolidated Controls:** Combine related settings such as device status, permissions, and updates into a single clear view to reduce complexity.

- **Real-Time Status and Alerts:** Display live device status using clear indicators and timely notifications.
- **Unified Data Management:** Standardize data actions such as viewing, deleting, and scheduling deletion across devices.
- **Data Categorisation:** Clearly distinguish between different data types, including tracking data and stored content.
- **Role-Based Access Control:** Support multiple user roles, including admin, adult, child, and guest, with appropriate permissions.
- **Cross-Device Compatibility**: Enable seamless control of a wide range of smart home devices within a single platform.

The Dashboard is designed to provide users with an efficient means to determine the status of their smart home devices from different perspectives, such as room locations, device types, device users, and data locations. These perspectives serve as the top-level entry points, allowing users to navigate to specific routes that provide views of individual devices and their associated status and settings. The structure of the dashboard and some of the routes to individual devices are illustrated in Figure 1. The design is tailored to enhance user experience, providing them with the necessary information in a clear, concise, and intuitive manner.

In a comprehensive analysis of various devices, key features were grouped into three main categories. These categories are derived from prior analysis conducted by the authors (Alghamdi et al., 2024), which examined security, privacy, and data management features across smart home devices, highlighting variations in how they are presented across different platforms. The Security category encompasses registration, authorisation, authentication, and security updates, which are essential for safeguarding user data. Privacy encompasses microphone access, location services, camera use, and usage habits, all of which are essential to protecting user privacy. Data Management comprises deleting specific or all recordings, scheduled deletions, and usage history, all of which are important for effectively managing user data.

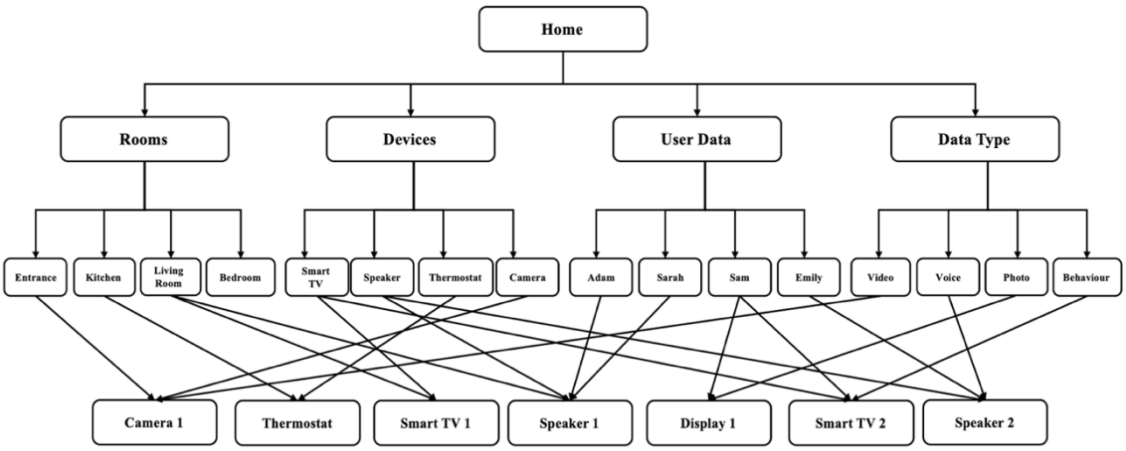

Figure 1: Dashboard Navigational Structure

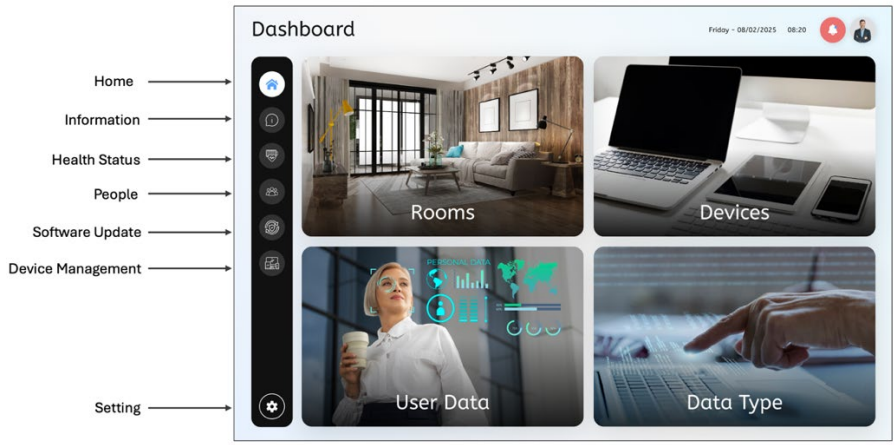
To ensure that the Dashboard prototype met widely recognised usability standards, its design was evaluated against Nielsen's ten usability heuristics (Nielsen, 1994). These heuristics provide a well-established framework for assessing user interface quality and supporting both novice and expert users. Most principles, including visibility of system status, match between the system and the real world, consistency and standards, user control and freedom, recognition rather than recall, aesthetic and minimalist design, and error prevention, were fully implemented. Advanced flexibility and detailed error recovery mechanisms were partially addressed due to the scope and fidelity of the prototype.

In addition to general usability principles, Human Computer Interaction for Security (HCISec) guidelines were incorporated to address challenges specific to security-oriented systems. These principles emphasise clear visibility of security status, the use of minimal technical jargon, and support for informed user decision-making. Prior research highlights the importance of these factors in security dashboards, particularly in helping users understand risks and manage protective controls effectively (Ibrahim et al., 2010).

4. An Overview of the Dashboard Prototype

The initial dashboard interface, shown in Figure 2, provides a clear and structured overview that enables users to manage smart home devices from multiple perspectives. The interface is organised around four main categories: Rooms**,** Devices**,** User Data, and Data Types, which reflect users' primary concerns when managing a smart home. In addition, a set of core navigation icons on the left of the screen support system management, providing access to the home view, informational guidance, device health status, household members, software update, device management, and system settings. Together, they enable users to monitor device status, manage permissions, receive alerts, and configure preferences through a consistent and easily accessible structure.



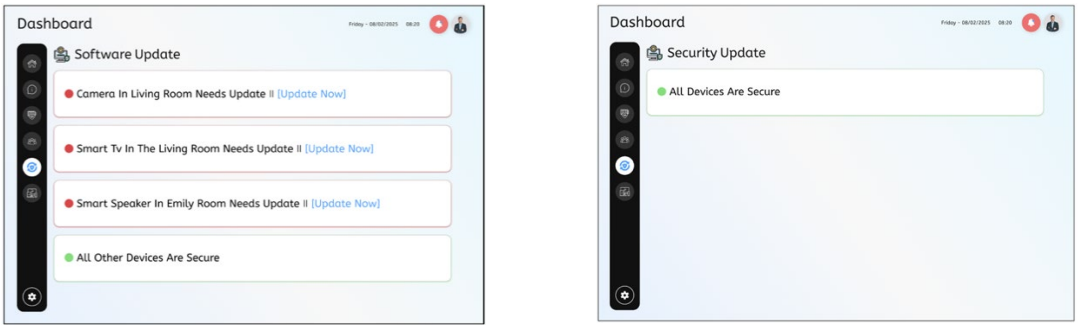


Figure 2: Home Interface

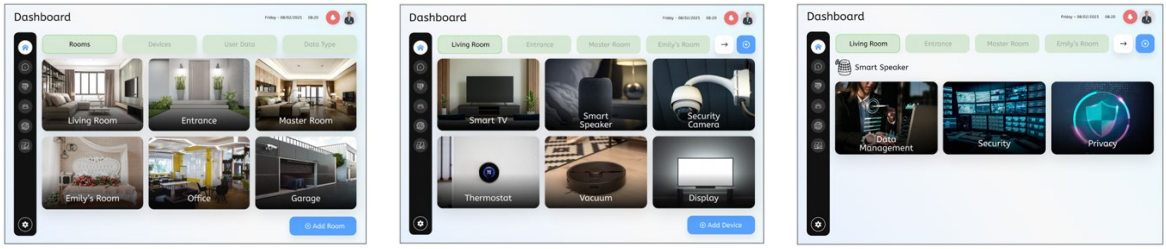

Figure 3 presents the software update interfaces, which provides an overview of update status across all connected smart home devices. Figure 3(a) highlights devices requiring immediate updates using red status indicators and provides an "Update Now" option to support prompt user action. In contrast, Figure 3(b) is displayed when all devices are fully updated, showing a single green status message. This conditional presentation ensures that users are shown only relevant information, reducing cognitive load and enabling efficient identification and resolution of security updates.

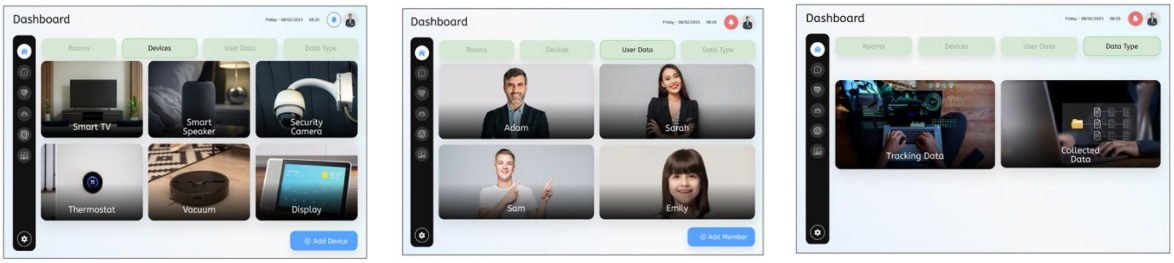
(a) (b)

Figure 3: Software Update Interfaces

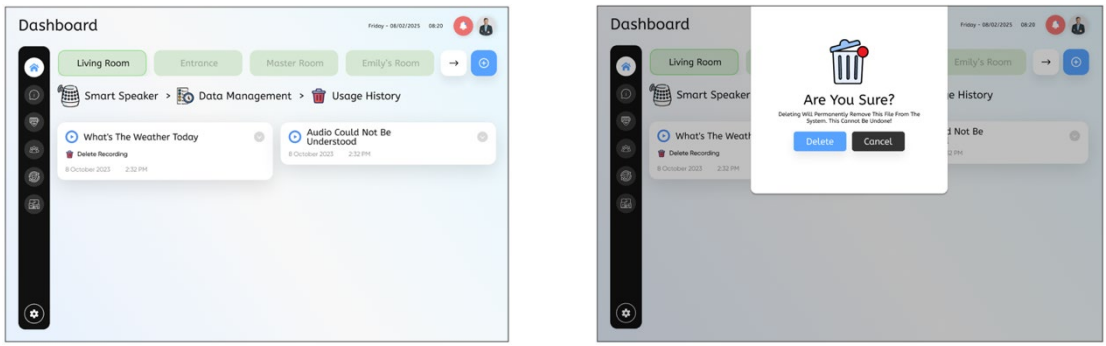


As illustrated in Figure 2, the Dashboard offers several routes by which users can explore their smart home configuration, namely via Rooms, Devices, Users, and Data Types. Each then offers a means to drill down to individual security and privacy settings. As an example, the Rooms view enables users to manage devices and privacy settings based on physical location within the home. As illustrated in Figure 4, users can navigate from a top-level overview of all rooms (4a), via devices in the room (4b), to a specific device within a selected room (4c), from which users can access device-specific Security, Privacy, and Data Management controls.

(a) (b) (c)

Figure 4: Rooms Interfaces route, showing: (a) rooms; (b) devices within a room; (c) settings on a device

Each of the other routes also expands in a similar manner. Space constraints prevent a full depiction of each route, but Figure 5 provides an illustration of the next level down within each one.



(a) (b) (c)

Figure 5: Alternative navigation routes, showing: (a) by device type; (b) by user type; (c) by data type

5. User Evaluation

A task-based user study was conducted to compare the user experience of the dashboard against three commercial platforms: Google Home, Amazon Alexa, and Apple HomeKit. These platforms were selected for comparison because they represent the three most widely adopted commercial smart home ecosystems. They support a broad range of consumer IoT devices and are commonly used to manage smart home environments through mobile applications. Evaluating the proposed dashboard against these platforms provides a realistic benchmark and enables comparison with interfaces that users are most likely to encounter in real-world smart home deployments. The evaluation aimed to assess how efficiently and effectively users could complete common security and privacy tasks, as well as their overall satisfaction with each platform, using a combination of quantitative performance metrics and qualitative feedback. Five scenarios were selected for the main evaluation, representing critical and common security and privacy interactions in smart home environments: Checking software updates; Managing smart speaker recordings; Muting microphones during meetings; Turning off location services across devices; and Reviewing security camera recordings. A set of task-specific interfaces were designed to reflect the interactions experienced by participants. The software update functionality was provided through the interface presented earlier in Figure 3. Figure 6 presents representative examples of the remaining interfaces used in the evaluation.

(a) (b)

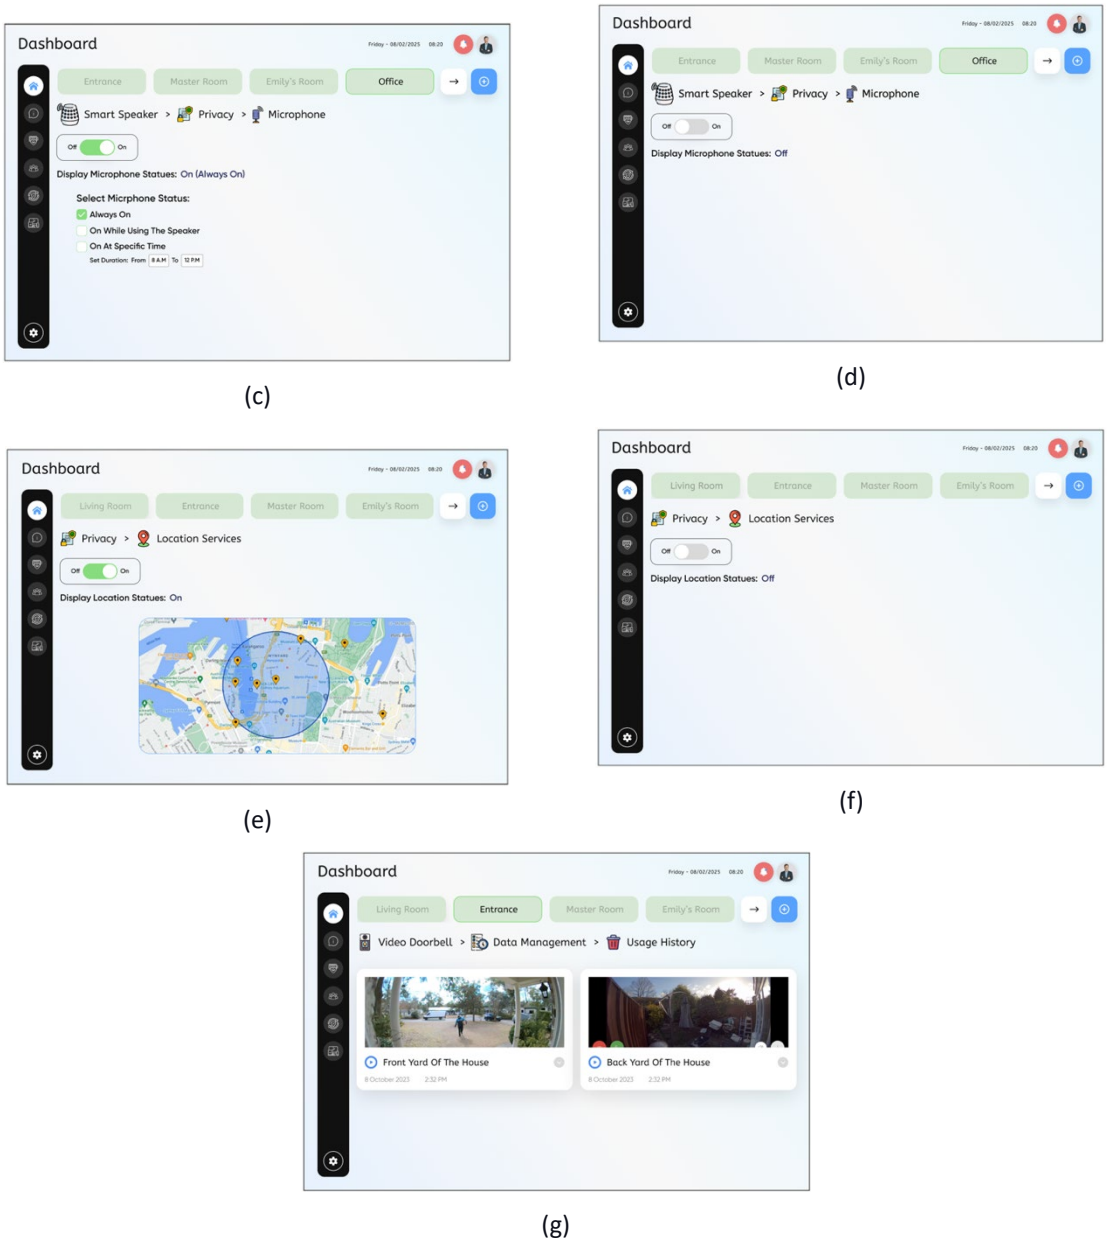


Figure 6: Task-based interfaces used during the evaluation: (a–b) managing smart speaker recordings; (c–d) muting microphones; (e–f) turning off location services; and (g) reviewing security camera recordings

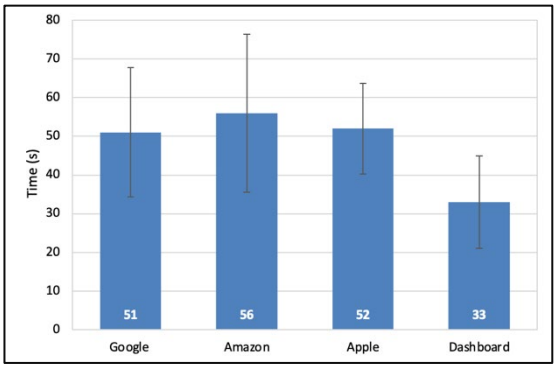
A total of 16 participants took part in the study. This sample size aligns with established usability evaluation guidelines, which indicate that 12–20 participants are sufficient to identify most usability issues and derive meaningful insights (Nielsen, 1994; Virzi, 1992). All participants owned at least two smart home devices and had sufficient English proficiency to understand task instructions and complete post-task questionnaires. Participants represented a range of digital literacy levels and backgrounds, reflecting a realistic smart home user population.

To ensure realism, real smart home devices, including smart speakers and security cameras, were configured and connected to their respective platforms. Devices were preloaded with realistic data, such as voice recordings, video recordings, and privacy-related settings. All tasks were performed on the same tablet device to maintain consistent experimental conditions. Participants completed the same set of tasks on each platform. The order of platform exposure was counterbalanced to reduce learning and order effects. During task execution, task completion time, number of clicks, and task success were recorded. After completing the tasks on each platform, participants completed the System Usability Scale (SUS) questionnaire and provided qualitative feedback.

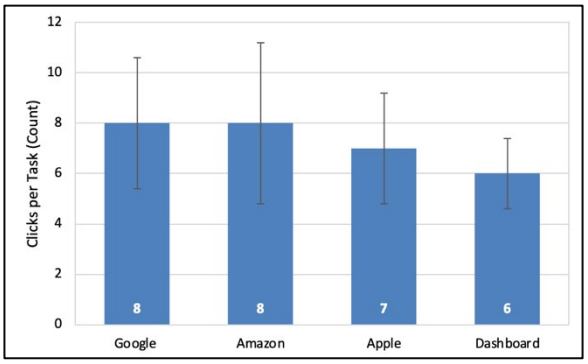
Efficiency is important for evaluating how easily and quickly users can complete tasks on different platforms and was assessed using task completion time and the number of clicks required per task.

- **Task completion time**: Figure 7(a) shows the dashboard achieving the fastest mean task completion time (33 seconds). Amazon consistently exhibited the slowest performance and the greatest variability, indicating less predictable task flows. Google and Apple had moderate performance but still required more time than the dashboard.
- **Clicks per task:** A similar pattern is observed in Figure 7(b), which presents the mean number of clicks per task. The dashboard required fewer interactions than other platforms, reflecting a more streamlined and direct interaction design. In contrast, Google and Amazon required the highest number of clicks, suggesting more fragmented navigation paths, while Apple occupied an intermediate position.



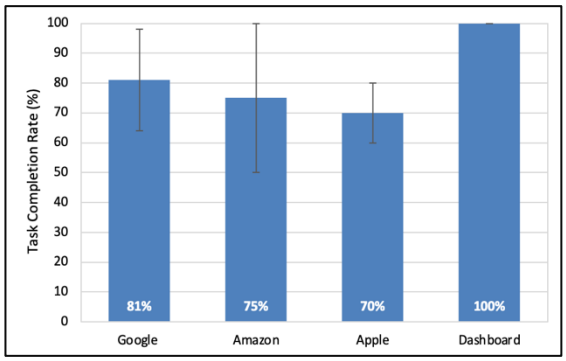
Overall, these results demonstrate that the dashboard supports more efficient task execution than Google, Amazon, and Apple by reducing both completion time and interaction effort.

Effectiveness was measured using task completion rates. Figure 7(c) shows that all participants successfully completed all tasks using the dashboard. In contrast, task failures were observed on all other platforms. Among these, Google achieved higher completion rates than Amazon and Apple, although with noticeable variability. Amazon exhibited the lowest and most inconsistent success rates, particularly for privacy-related tasks, while Apple showed more stable but generally lower completion rates. These findings indicate that, unlike the dashboard, existing platforms do not consistently support successful task completion across users.



Finally, user satisfaction was evaluated using the System Usability Scale (SUS). As illustrated in Figure 7(d), the dashboard demonstrates the highest perceived usability, with a mean SUS score of 86, clearly outperforming Google, Amazon, and Apple. Amazon received the lowest usability ratings and the highest variability, indicating inconsistent user experiences. Google and Apple achieved moderate scores, with Apple showing more consistency but lower overall usability.

Qualitative feedback highlighted the dashboard's intuitive navigation, unified structure, and clarity of security and privacy controls. Participants frequently described the dashboard as "easy," "straightforward," and "clear," emphasising the benefit of managing all devices and data in a single interface. Many participants stated they would recommend the dashboard to others, including non-technical users. In contrast, Google, Amazon, and Apple were commonly described as confusing or overly complex, with privacy settings distributed across multiple menus. Several participants reported giving up on some tasks when using commercial platforms, particularly those involving recordings or privacy controls.



The task failures observed in these platforms appear to be largely associated with fragmented interface structures and the distribution of security and privacy settings across multiple layers of the interface. Participants frequently reported difficulty locating specific privacy controls, such as voice recording management or location permissions, which were often buried several levels within the interface hierarchy. By contrast, the proposed dashboard consolidates these functions within clearly labelled categories. This structure reduces navigation complexity and helps users more easily locate key security and privacy controls.

6. Conclusion

This paper presented the design and evaluation of a harmonised dashboard for managing security and privacy in smart home environments. As smart homes increasingly consist of heterogeneous devices operating across multiple ecosystems, users are often required to manage complex security and privacy settings through fragmented and inconsistent interfaces. This work addressed these challenges by proposing a unified, user-centred dashboard that integrates security, privacy, and data management controls across devices.

A task-based user evaluation compared the proposed dashboard with three widely used commercial platforms, with the results demonstrating clear advantages of the dashboard across all evaluated dimensions. Participants completed tasks more efficiently, required fewer interactions, and achieved higher task success rates when using the dashboard. Notably, all participants successfully completed all tasks on the dashboard, while failures were observed on the commercial platforms, particularly for privacy-related scenarios. User satisfaction results further reinforced these findings. The dashboard achieved the highest SUS scores with low variability, indicating strong perceived usability and consistent user agreement. Qualitative feedback highlighted the dashboard's intuitive navigation, unified structure, and ability to support confident and informed decision-making. In contrast, other platforms were frequently described as complex, fragmented, and difficult to navigate.

Overall, the findings demonstrate that a harmonised, user-centred dashboard can substantially improve how users manage smart home security and privacy. By reducing complexity and providing consistent access to critical controls, the proposed approach supports more efficient, effective, and satisfying user interactions. This work highlights the importance of integrating usability considerations into the design of security-critical systems and provides a strong foundation for future research into scalable deployment and long-term use of unified smart home management interfaces.

Ethics Declaration: The study was approved by the School of Computer Science Research Ethics Committee [CS-2024-R21]. Data was collected anonymously and participants were informed that they could withdraw at any time.

AI Declaration: No AI tools were used in this paper.

Abstract: Traditional authorization mechanisms such as passwords, smart cards, and conventional biometrics remain vulnerable to spoofing, replay, and social-engineering attacks, particularly in IoT and cloud environments. Physiological biometrics, including electrocardiogram (ECG) and electromyography (EMG) signals, offer stronger resistance to forgery because of their biological origin while also capturing emotional and behavioral context. This study presents AlMuwathiq, an emotion-based multimodal authorization system that integrates ECG and EMG signals to support adaptive access-control decisions. Real physiological signals were collected and labeled using the Self-Assessment Manikin across five emotional states. After signal preprocessing and feature extraction, multiple machine learning models were evaluated, with a focus on explainable learning algorithms. Experimental results indicate that Random Forest and XGBoost achieved the most stable classification performance. The trained models were integrated into a real-time platform where access control authorization decisions are determined by emotional rules. The findings demonstrate that emotion-aware physiological authorization can enhance security, reliability, and context awareness in modern cybersecurity systems. This study thus advances the current state of the art in access control systems, especially in mission-critical infrastructures.

Keywords: Emotion-based authorization, Physiological biometrics, Electrocardiogram (ECG), Electromyography (EMG), Multimodal authentication, Affective computing, Machine learning, Access control, Cybersecurity

1. Introduction

Authentication is a fundamental security mechanism that verifies users' identities and grants access only to authorized individuals. It plays a critical role in protecting systems and sensitive data from unauthorized access. This process typically relies on three main factors: something the user knows (such as passwords), something the user has (such as tokens or smart cards), and something the user is (biometric characteristics). While these methods are widely used due to their simplicity and ease of implementation, they also suffer from several limitations. Password-based authentication, for example, is highly vulnerable to brute-force attacks, phishing, and credential theft (Florêncio & Herley, 2007). Similarly, token-based methods may fail if the physical device is lost, stolen, or duplicated, which creates additional security risks. There are many authentication challenges in the Internet of Things (IoT), including security risks that might threaten network security. Examples include man-in-the-middle attacks, in which an attacker sits between two parties and intercepts data as it is transferred, and brute-force attacks, which repeatedly guess passwords. In addition, there are privacy concerns; biometric data such as iris scans, fingerprints, and voice recognition can be collected, and the user's location can be saved with the data. This can lead to unauthorized tracking, which is a major privacy issue. Moreover, there is a concern about flexibility, as many devices require authentication to maintain a high level of security and support intelligent solutions such as artificial intelligence. Resource limitations are another challenge, since devices often have limited memory and battery power (Alsheavi et al., 2024).

A typical user authentication process follows a structured sequence: an identity claim, credential submission, and verification against stored data (Adeyemi & Ithnin, 2012). If the credentials match, access is granted; otherwise, it is denied. However, traditional systems often rely on single-factor authentication, which significantly increases the risk of unauthorized access. Modern systems have therefore shifted toward multi-factor authentication (MFA), combining multiple verification methods to improve security. Despite these improvements, authentication alone is not sufficient. Authorization plays an equally important role, as it determines what actions a verified user is allowed to perform within a system. Authorization ensures that users only access resources that match their permission level. As highlighted in the project, authorization mechanisms follow specific rules that define access based on factors such as roles, policies, and system conditions. Common models include Role-Based Access Control (RBAC), Attribute-Based Access Control (ABAC), and Policy-Based Access Control (PBAC). However, traditional authorization methods are often static and do not adapt to real-time conditions. In modern environments such as IoT and cloud systems, this creates serious challenges. Devices in these environments are often resource-constrained and may lack proper security configurations, making it difficult to enforce consistent access control policies (Khan et al., 2022). As a result, even if authentication is

successful, weak authorization can still lead to security breaches. To address these limitations, researchers have explored more advanced profiling-based mechanisms that extend beyond static authentication and focus on continuously understanding user behavior and characteristics. These profiling approaches include multiple dimensions. User profiling enables adaptive systems to learn preferences over time through explicit and implicit data collection, thereby improving personalization and decision-making accuracy. Physiological profiling uses biological signals such as EEG, ECG, and GSR to measure cognitive states, such as attention and engagement, enabling systems to detect deeper user conditions. Sociological profiling examines how social structures and behavioral mechanisms influence human actions, highlighting ethical concerns when human behavior is oversimplified into machine-like processes. Linguistic profiling treats speech and writing patterns as a digital fingerprint by analyzing vocabulary, tone, and typing behavior for identity verification. Psychological profiling focuses on personality traits, such as the Big Five model, and is often applied to machine learning systems to infer behavioral tendencies, though it raises concerns about bias and fairness. Behavioral profiling enables continuous authentication through patterns such as typing, touch gestures, movement, and eye behavior, making identity verification ongoing rather than one-time. Together, these profiling mechanisms create a more adaptive and multi-dimensional understanding of users, but they also introduce challenges related to privacy, ethics, and data interpretation.

Building on these advancements, researchers have explored biometric-based approaches, particularly physiological biometrics. Unlike traditional biometrics such as fingerprints or facial recognition, physiological signals originate from within the human body, making them more secure and difficult to replicate. Two important physiological signals are the electrocardiogram (ECG) and electromyography (EMG). ECG signals measure the electrical activity of the heart, producing waveform patterns that are unique to each individual. EMG signals, on the other hand, measure muscle activity and reflect how muscles respond during movement or expression. As stated in the project, these signals “are difficult to forge and contain individual-specific patterns,” making them highly suitable for authentication and authorization systems (Israel et al., 2005; Jain et al., 2016). In addition to identity verification, physiological signals provide valuable insights into a user's emotional state. This concept is supported by research in affective computing, which focuses on detecting and interpreting human emotions using computational methods. According to the project, physiological signals such as ECG and EMG can reflect emotional states like calmness, stress, and frustration, which may influence user behavior during access attempts. For example, a sudden increase in heart rate or muscle tension may indicate stress or abnormal conditions. Incorporating this emotional information into authorization decisions allows systems to become more context-aware and adaptive (Picard, 1997). Several studies have explored the relationship between ECG signals and emotional states. ECG-based emotion recognition typically analyzes features such as heart rate variability, waveform morphology, and frequency-domain characteristics. Similarly, EMG signals—especially those collected from facial muscles—can be used to detect emotions such as happiness, anger, and sadness by analyzing muscle activation patterns. Machine learning techniques play a crucial role in this process. Algorithms such as Support Vector Machines (SVMs), Random Forests, K-Nearest Neighbors (KNNs), and deep learning models are commonly used to classify emotional states based on extracted features. These models learn patterns from labeled datasets and can achieve high accuracy in recognizing different emotions. To further improve system performance, researchers have introduced multimodal biometric systems that combine multiple physiological signals. Instead of relying on a single signal, multimodal systems integrate ECG and EMG data to enhance accuracy and reliability. As mentioned in the project, combining multiple signals helps “reduce noise, improve classification performance, and increase resistance to spoofing attacks”. This approach is particularly useful in real-world scenarios where signal quality may vary due to movement or environmental conditions. Multimodal systems also provide better robustness, as they rely on multiple sources of information rather than a single point of failure (Ross & Jain, 2004).

Despite the advantages of physiological biometric systems, several limitations still exist in current research. Many existing studies focus on ECG or EMG signals independently, without fully exploring the benefits of combining the two modalities in a unified framework. In addition, most traditional systems rely primarily on identity verification and do not consider the user's emotional or behavioral context during access attempts. This creates a gap where authorized users may still gain access under abnormal or high-risk conditions, such as stress or coercion. Furthermore, challenges such as signal variability, noise interference, and privacy concerns continue to affect the reliability and real-world applicability of these systems. While preprocessing and machine learning techniques have improved classification performance, there is still a need for systems that can operate reliably in dynamic environments while maintaining user privacy and security (Khan et al., 2020; Meltzer & Luengo, 2023; Wang et al., 2025). Therefore, this study builds on existing research by proposing a multimodal authorization approach that integrates both ECG and EMG signals with emotional state recognition. By combining multiple

physiological signals and incorporating emotional awareness into access control decisions, the proposed system aims to provide a more secure, adaptive, and context-aware authorization mechanism compared to traditional methods.

2. Background of the Study

This section reviews existing studies related to electrocardiogram (ECG) and electromyogram (EMG) biosignal technologies, with a focus on privacy, authorization mechanisms, and data security challenges. It examines identified risks, such as unauthorized access and re-identification, and emphasizes the need for structured authorization and forensic-aware frameworks to support the secure and ethical management of biosignal data within wearable and remote healthcare systems. With the rapid growth of wearable and remote healthcare technologies, the privacy and authorization of biosignals such as electrocardiogram (ECG) and electromyogram (EMG) data have become increasingly critical research concerns. These signals are widely used in clinical environments and biomedical research for their diagnostic value; however, their high sensitivity raises serious concerns about data access, misuse, and patient privacy. Prior studies have shown that ECG data, in particular, can reveal uniquely identifiable and personal information. Wang et al. (2025) demonstrated that ECG datasets shared without proper anonymization are vulnerable to re-identification attacks, emphasizing the need for strict authorization mechanisms and controlled access. Similarly, Meltzer and Luengo (2023) highlighted that the intrinsic uniqueness of ECG signals makes them comparable to biometric identifiers, meaning that even short recordings can expose sensitive health-related details if accessed without appropriate safeguards.

From a legal and ethical perspective, healthcare regulations such as the Health Insurance Portability and Accountability Act (HIPAA) mandate explicit patient authorization before biosignal data can be accessed or shared. These regulatory frameworks emphasize accountability and informed consent, particularly when ECG and EMG data are collected, processed, or transmitted through online and wearable systems. Overall, the literature consistently underscores the importance of robust authorization and privacy controls for the ethical, secure, and lawful management of biosignal data, especially as wearable medical devices become increasingly integrated into modern healthcare infrastructures. Although the advantages of ECG and EMG are based on systems, there are multiple challenges from different perspectives. From a security perspective, wearable and IoT environments can be vulnerable to unauthorized access and inadequate protection, putting sensitive data at high risk. From a technical side, these signals can be affected by noise, sensor placement, and changes in the user's condition, which may reduce accuracy. In addition, traditional authorization methods have limitations, such as the risk of stolen access cards or granting users more permissions than needed. To address these issues, our system (AlMuwathiq) uses a combination of ECG and EMG signals to create a more secure and reliable approach. It improves accuracy through signal processing and machine learning, and it makes smarter authorization decisions by also considering the user's emotional state, making the system more adaptive and secure.

3. Methodology

The methodology followed in this study is illustrated in the operational framework shown in Figure 1. The framework consists of a setup phase and three main phases covering dataset development, signal preprocessing, machine learning experimentation, and the final integration of the authorization platform. Each stage reflects the actual workflow used to implement the access control system (hereinafter, the AlMuwathiq system).

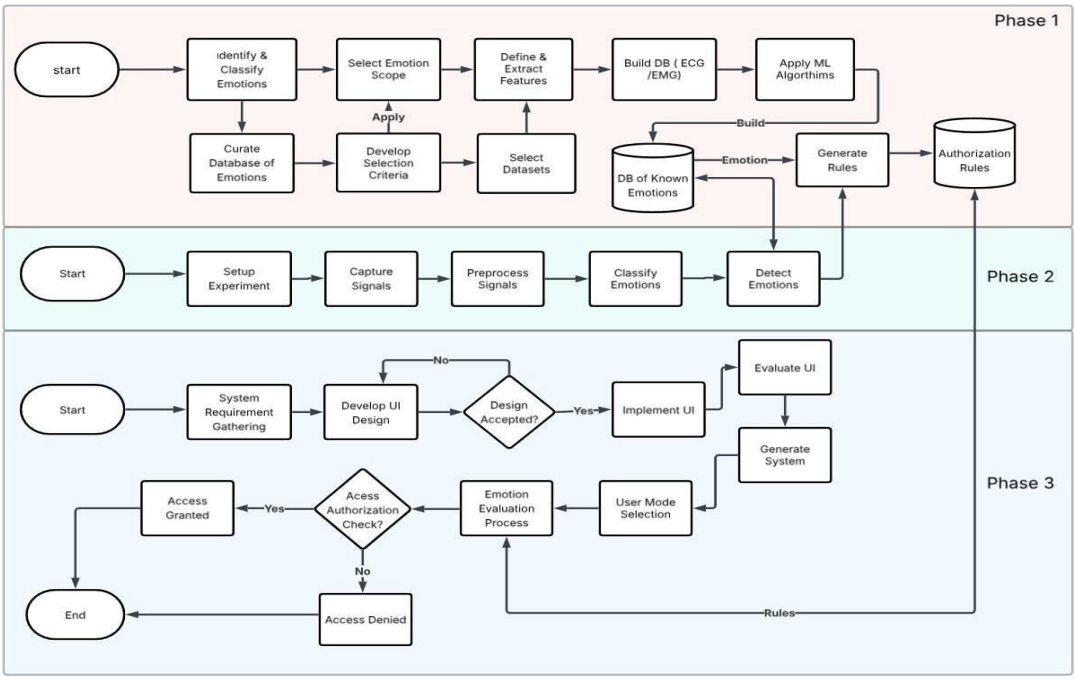

Figure 1: Operational Framework

3.1 Setup Phase

In the setup phase, the ECG and EMG sensors were carefully connected to the hardware device and allowed to ensure reliable signal acquisition. The Arduino was configured to read the analog inputs from both sensors and transmit the recorded values for further processing. The software environment, including Python and required packages, was prepared to support the preprocessing, feature extraction, and machine learning stages of the study. Table 1 provides an overview of all components used in the system configuration.

Table 1: Tools, Sensors, and Software Used in the System

Component	Description
ECG Sensor	Captures electrical heart activity through analog pin A0
EMG Sensor	Measures muscle activation through analog pins A1 and A3
Arduino Board	Acquires raw signals and transmits them via serial output
Python	Used for preprocessing and machine learning
Platform	Allows users to upload signals and receive authorization results

3.2 Phase I: Dataset Development

In this phase, real ECG and EMG signals were collected from users using the configured hardware device. Signals were captured in real time and exported as CSV files. Each recording was labeled with one of the five emotional categories defined in the system: Calm, Amused, Satisfied, Gloomy, or Frustrated. To ensure labeling is correct, the Self-Assessment Manikin (SAM) was administered after each recording. The SAM values were used as ground-truth labels for the machine-learning dataset (Handayani et al., 2015).

3.3 Phase II: Signal Preprocessing and Feature Extraction

Raw ECG and EMG signals contain noise and irregularities; therefore, a preprocessing pipeline was implemented. Signal cleaning included:

- Bandpass filtering to isolate relevant frequency ranges

- Notch filtering to remove 50/60 Hz power-line noise
- Smoothing and denoising to reduce signal artifacts
- Windowing by dividing the signal into equal segments

After preprocessing, features were extracted from each window. The features listed below match the actual feature sets used

Table 2: ECG Feature Set Extracted

Feature Category	**Extracted Features**
Time-Domain	Mean, Standard Deviation (STD), Root Mean Square (RMS), Peak-to-Peak
Frequency-Domain	Power Spectral Density (PSD-based features), Dominant Frequency
Statistical Features	Variance, Skewness, Kurtosis
Morphological	R-peak information (from processed ECG waveform when applicable)

Table 3: EMG Feature Set Extracted

Feature Category	**Extracted Features**
Time-Domain	Mean Absolute Value (MAV), Root Mean Square (RMS), Waveform Length (WL)
Frequency-Domain	Median Frequency, Mean Frequency
Statistical	Variance, Log Energy Entropy
Signal Shape Features	Slope Sign Changes (SSC), Zero Crossings (ZC)

3.4 Phase III: Machine Learning Experimentation

The extracted features were used to train and evaluate multiple classification models. The algorithms tested include:

- Random Forest
- XGBoost
- Support Vector Machine (SVM)
- K-Nearest Neighbors (KNN)

Model performance was evaluated using accuracy, precision, recall, F1-score, and confusion matrix. Two experiments were carried out: an initial experiment and an optimized version after refining the preprocessing pipeline and dataset structure. The following table summarizes the general performance patterns of the models based on your results.

Table 4: Model Evaluation Overview

Model	**Performance Summary**
Random Forest	Strong and stable performance; among the highest accuracy and F1-score in both experiments
XGBoost	High accuracy and strong performance after optimization
SVM	Moderate performance; sensitive to noise and variability
KNN	Lowest performance; not suitable for this dataset

3.5 Authorization System Development

In this final phase, the trained models were integrated into the AlMuwathiq authorization platform. The system allows users to upload an ECG or EMG CSV file, select a classification model, and receive an emotion prediction, after which access is automatically granted or denied based on predefined emotional rules.

Emotional authorization rules used:

- Calm, Satisfied, Amused → Access Granted
- Gloomy, Frustrated → Access Denied

4. Discussion

The results of this project demonstrate that integrating privacy-aware authorization mechanisms into biosignal-based systems is both necessary and feasible. The findings confirm that ECG and EMG signals are not only valuable for health monitoring and authentication, but also pose significant privacy risks when handled without strict access controls. Throughout the project, the implemented authorization approach showed that limiting access based on predefined conditions and user roles can effectively reduce the exposure of sensitive biosignal data. This supports the argument presented in the literature that biosignals should not be treated as ordinary medical data, but rather as high-risk biometric-like information requiring stronger protection.

From a system perspective, the final project successfully translates theoretical privacy and authorization concerns into a practical framework. The results indicate that combining authorization logic with biosignal processing enhances data security without disrupting system functionality or usability. This balance is critical in wearable and remote healthcare environments, where continuous data collection is required. Moreover, the project highlights that simple anonymization alone is insufficient, as ECG characteristics remain identifiable even in limited samples. By enforcing controlled access and explicit authorization, the system aligns more closely with legal and ethical requirements such as patient consent and accountability, as emphasized by healthcare regulations.

Overall, the project outcomes validate the proposed approach and demonstrate its relevance to real-world applications involving wearable medical devices. The results contribute to existing research by showing how authorization mechanisms can be practically embedded within biosignal systems rather than treated as an external policy layer. While the project is limited to a controlled experimental setup, it establishes a strong foundation for future work, including real-time deployment, larger datasets, and integration with advanced security frameworks. In conclusion, the results confirm that privacy-preserving authorization is a critical component for the secure and ethical use of ECG and EMG technologies, reinforcing the overall objectives of the final project.

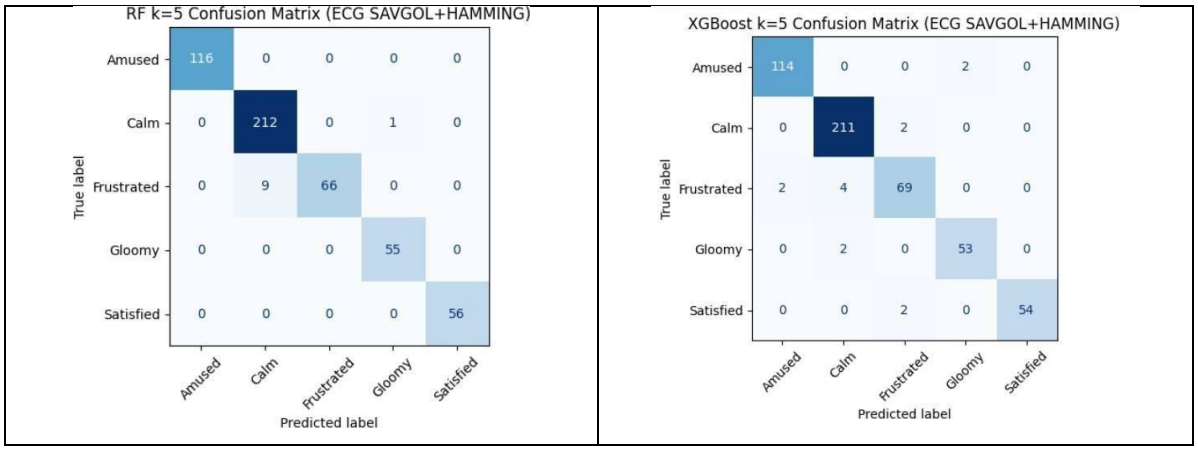

Figure 2-3: Confusion Matrix for Random Forest & XGBoost (k=5) using ECG SAVGOL+HAMMING

The confusion matrix analyses provide strong evidence of the effectiveness and stability of the proposed multimodal emotion-based authorization framework. Across both ECG and EMG modalities, the evaluated models demonstrate a dominant diagonal structure, indicating that the majority of samples were correctly classified into their respective emotional categories. In particular, the ECG-based results using the SAVGOL+HAMMING preprocessing configuration show consistently high recognition performance for all five emotional states. The limited misclassifications observed—primarily between Frustrated and Calm—suggest

that these emotions share partially overlapping physiological characteristics, a phenomenon commonly reported in affective computing literature. Nevertheless, the overall classification stability indicates that the selected ECG preprocessing pipeline preserves discriminative emotional features while remaining robust.

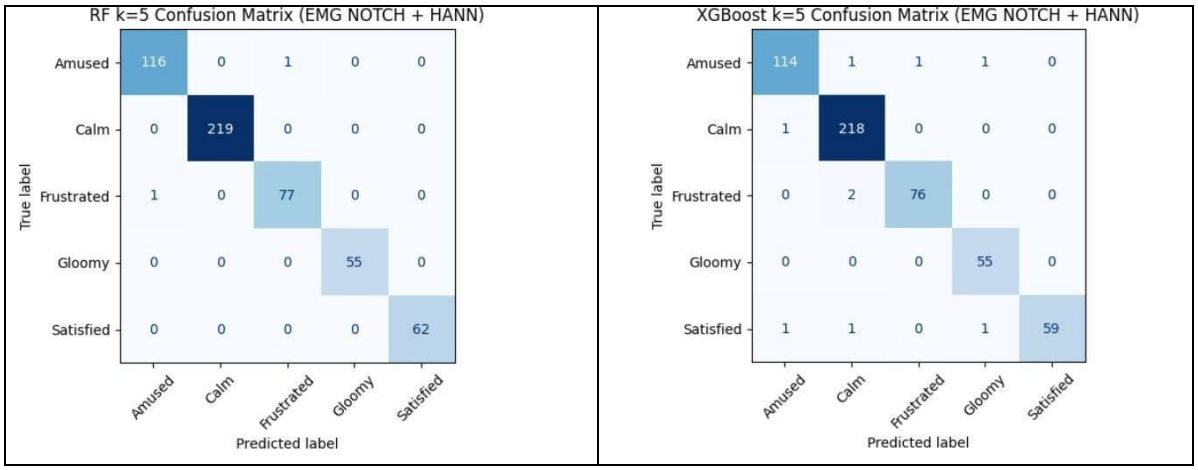

Figure 4-5: Confusion Matrix for Random Forest & XGBoost (k=5) using EMG NOTCH+HANN

A similar trend is observed for EMG-based emotion recognition, where the NOTCH+HANN preprocessing configuration yields highly reliable results. The Random Forest classifier exhibits near-perfect diagonal dominance, with only two isolated misclassifications, indicating exceptional consistency and generalization capability. While the XGBoost model also achieves strong performance, it displays slightly increased confusion among certain emotional classes, particularly Amused and Satisfied. This difference highlights the comparative stability of Random Forest in handling EMG signal variability and noise, reinforcing its suitability for biosignal-driven authorization tasks. Overall, the results suggest that EMG signals, when appropriately filtered and windowed, can offer highly distinctive emotional patterns that support secure and accurate classification.

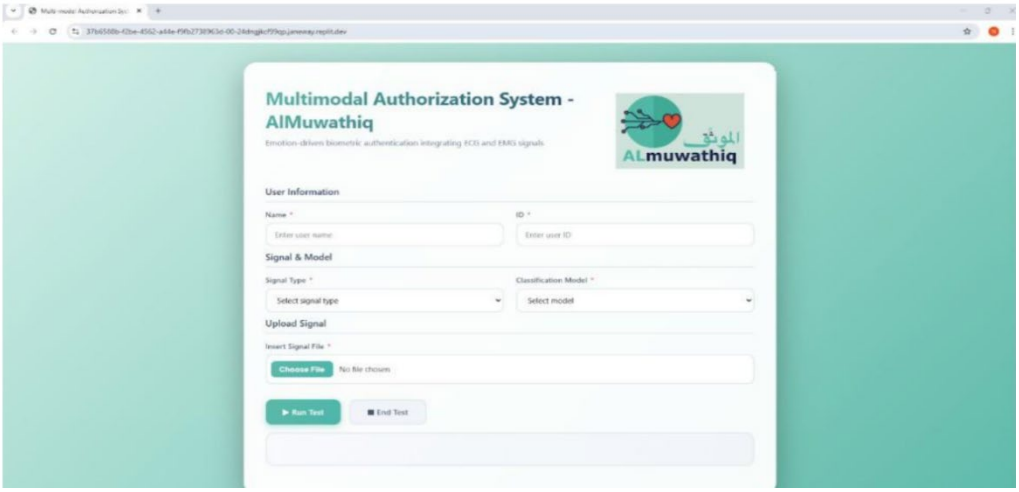

Figure 6: User Interface of the AlMuwathiq Multimodal Authorization System

Beyond model performance, these results directly validate the design and functionality of the AlMuwathiq Multimodal Authorization System. The system successfully translates emotion classification outputs into real-time authorization decisions through a clear rule-based mechanism. The user interface results demonstrate that detected emotions are transparently mapped to access outcomes, ensuring both usability and explainability—key requirements for authorization systems in sensitive environments. The correct handling of both access-granted and access-denied scenarios confirms that the system operates as intended, enforcing emotional-state-based authorization without ambiguity. Taken together, the results confirm that the proposed framework is not only technically sound but also practically deployable, offering a secure, interpretable, and privacy-aware approach to biosignal-based authorization suitable for real-world applications. In summary, this methodology outlines the complete scientific workflow of the AlMuwathiq system: real signal acquisition, SAM-based emotional labeling, structured preprocessing, feature extraction, machine learning experimentation, and final

system deployment. All steps described directly reflect the project implementation without adding any external methods or assumptions.

5. Future Studies and Recommendations

Future work on the proposed AlMuwathiq system will focus on expanding the dataset and improving the stability of emotion classification across a wider range of users. Since the current dataset was collected from a limited group, increasing the number of participants would strengthen the reliability and generalization of the emotional categories. Additional data samples would also support further refinement of the preprocessing pipeline, particularly in reducing naturally occurring noise in ECG and EMG recordings. In addition, enhancing the performance of the existing machine-learning models. While Random Forest and XGBoost demonstrated strong results in the evaluation, further optimization of the feature sets and preprocessing techniques may lead to even more consistent outcomes. This can include refining windowing strategies or exploring additional parameters within the current feature categories already used in the project. Moreover, future versions of the system could focus on improving the user experience of the authorization platform. This includes streamlining the signal upload process, improving the visualization of emotional output, and ensuring the authorization decision is clearly communicated to the end user. Integrating additional testing scenarios within the platform may also help validate the system's behavior in different usage conditions. Finally, future studies should examine how the emotional states captured by ECG and EMG signals evolve across multiple sessions and different time periods. This will help maintain long-term consistency in emotional biometrics and evaluate whether the same emotional patterns remain stable across repeated use. Such insights would help improve the system's reliability and position emotion-based authorization as a viable complement to traditional authentication methods.

6. Conclusion

The concept of user and entity authorization has been widely deployed for access control in mission-critical infrastructure. Existing studies have shown the need for a dynamic mechanism that considers the user's emotional and psychological state before authorization. This study developed an innovative mechanism for entity authorization that considers the user's emotional state using a widely accepted emotion classification metric. The results of a comprehensive experimental and testing process further validate the study's proposition and establish a reliable accuracy threshold. The results of this study, therefore, demonstrate that both ECG and EMG signals from users can be leveraged for authorization. Furthermore, this probability opens the possibility of integrating emotion-based authorization as a complementary component in physical security.

Ethics Declaration: This study did not require ethical approval because no human or animal subjects were involved. The authors affirm that no human research participants were involved in this study; hence, it is not applicable.

AI Declaration: The Authors declare that AI was not used to write the manuscript and that the content represents the authors' original writing, except where an AI tool was used to edit the manuscript to enhance clarity.

Beyond the Dashboard: Unseen Cybersecurity Vulnerabilities Caused by User Behaviour in Connected and Autonomous Vehicles Systems

Dimah Almani
Shaqra University, Saudi Arabia

dimah.almani2@nottingham.ac.uk
dalmanea@su.edu.sa

Abstract: As Connected and Autonomous Vehicles (CAVs) become increasingly integrated into Intelligent transportation systems, cybersecurity is no longer limited to protecting onboard technologies—it must also account for the everyday digital behaviours of the users who manage and interact with these vehicles. This paper introduces the concept of the "behavior-driven cyber-risk layer" in CAVs, a hidden but critical vulnerability surface created not by system flaws, but by routine user actions surrounding the vehicle ecosystem. Although CAVs rely on advanced communication, sensors, and cloud connectivity, small human habits—such as ignoring software update alerts, connecting infotainment systems to insecure personal devices, oversharing trip information, accepting unverified apps, or reusing credentials across applications—can undermine even the most sophisticated vehicle security architectures. This study examines how these seemingly minor behaviors interact with CAVs' security mechanisms, including Vehicle-to-Vehicle (V2V) and Vehicle-to-Infrastructure (V2I) communications, certificate-based authentication, and onboard digital systems. We show how attackers exploit predictable user routines—such as uploading navigation routes to cloud platforms, pairing phones via Bluetooth, or trusting unsolicited messages that appear to come from vehicle services—to introduce false data, manipulate trust decisions, or gain unauthorized access. Through real-world scenarios, we demonstrate how small mistakes can escalate into larger risks, enabling targeted tracking, spoofed messages, or remote access to vehicle functions. Instead of treating these behaviours as psychological tendencies, this paper frames them as operational cybersecurity weaknesses that directly affect the safety and reliability of CAVs. To illustrate, existing user awareness strategies are evaluated to highlight why they fail in high-convenience environments, where users expect seamless automation and often overlook security steps. Finally, a set of human-centered cybersecurity practices are proposed that are designed specifically for CAVs ecosystems, including simplified interface warnings, context-aware security prompts, secure-by-default connectivity options, and automated verification mechanisms that reduce reliance on user judgment. By revealing the hidden risks embedded in everyday interactions, this work emphasizes that the cybersecurity of CAVs depends not only on the technology itself, but also on how people engage with it.

Keywords: Vulnerabilities, Behaviours, CAVs, Security, Transportation, V2V, Attacks, Safety, Awareness

1. Introduction

In Intelligent Transportation Systems (ITS), Connected and Autonomous Vehicles (CAVs) form the core of the smart driving system, and they are rapidly becoming the primary component in ITS. In CAVs, the vehicles communicate with each other, forming Vehicle-to-Vehicle (V2V) communications, and communicate with the infrastructure around them, forming Vehicle-to-Infrastructure (V2I) communications (Falcone et al., 2007). CAVs rely on a sophisticated system of Onboard Units (OBUs), including sensors, radar, lidar, camera, and digital services to enable different levels of automation, efficient driving, and user safety. The automation levels in CAVs range from low level (0) to high level (5) (SAE International, 2021), and in each level the vehicle has different features as shown in Figure1. While significant research efforts have focused on securing vehicle hardware, communication protocols, and backend infrastructures, cybersecurity in CAVs cannot be fully addressed by technical mechanisms alone (Almani, 2024). In addition, much attention has been given to protecting (V2V) and (V2I) communications, certificate-based authentication, and onboard control systems, but a critical vulnerability surface remains largely overlooked: the everyday digital behaviors of users interacting with the vehicle ecosystem. The main contribution of this paper is a structured analysis of how predictable user behaviors interact with CAV security mechanisms and create exploitable attack paths. Through real-world-inspired scenarios, we demonstrate how attackers leverage these behaviors to introduce false data, manipulate trust decisions, or gain unauthorized access to vehicle systems. Rather than framing these behaviors as psychological shortcomings, we treat them as operational cybersecurity weaknesses that directly impact safety, reliability, and trust in CAV environments.

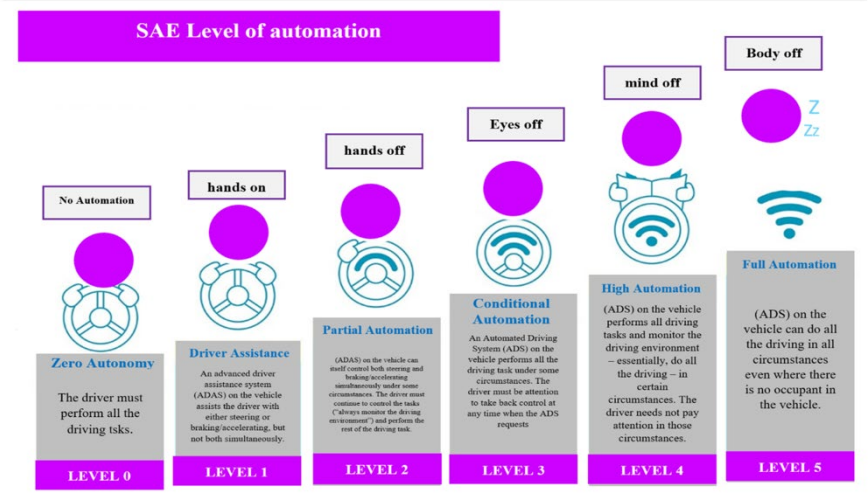

Figure 1: SAE Levels of Automation (SAE International, 2021)

2. Background: Security Architecture of CAV Ecosystems

In ITS, the more vehicles are connected, the more they will be able to obtain drastic enhancements in driving environment safety and traffic flow optimization, and consequently, offer a full set of services for passengers and drivers. CAVs operate within a highly interconnected digital ecosystem composed of multiple security-sensitive components. These include onboard electronic control units (ECUs), infotainment systems, wireless communication modules, mobile devices, and cloud-based services (Khanmohamadi & Guerrieri, 2024). This section discusses the key concepts of CAVs networks and their integration into autonomous vehicles, highlighting the importance of network infrastructure and connectivity. Recent research on CAV cybersecurity has primarily focused on securing communication protocols, intrusion detection mechanisms, and cryptographic authentication systems. However, relatively limited attention has been given to the role of user interaction and behavioral patterns in shaping the overall attack surface of CAV ecosystems. Several studies highlight the growing importance of human factors in cyber-physical systems, yet their integration into vehicle cybersecurity architectures remains largely unexplored.

2.1 Communication and Trust Mechanisms

CAVs are highly dependent on V2V communications as well as V2I communications to exchange safety messages, traffic messages, as well as environment messages. These communications often employ certificate-based authentication frameworks, such as public key infrastructure, to verify message integrity as well as authenticity (Almani et al., 2022). Messages are often deemed to be from trustworthy sources if they appear to be so after cryptographic analysis. Although these measures can and indeed are intended to prevent attacks by malicious third parties, they tacitly presuppose that the rest of the digital world, and specifically user-controlled interfaces, will be safe (Zhang et al., 2021).

2.2 User Interaction Points

Modern CAVs present various interaction opportunities for the user, such as infotainment systems, mobile applications, cloud-based dashboards, and the use of external services. The most common interactions occur through the smartphone via Bluetooth and/or USB connectors, data synchronization from navigation systems to the cloud, as well as the installation of applications. These interaction points serve as the bridges between the safe interior of the vehicle and the larger, more uncontrolled digital world. These interaction zones can often rely for their security upon the choices of users, making it an essential area in terms of the overall attack surface (Chattopadhyay et al., 2020). From the above discussion, it can be noticed that the CAV ecosystem is a complex, multi-layered environment that depends not on a single layer for security but rather a complex array that comprises various levels such as physical devices, networks, application-level systems, cloud services, backend services, in addition to those managed by the user for interaction. Each level has a unique mechanism for protection, which in turn faces a specific source for threats but, at the same time, could affect the entire environment's reliability (Bendiab et al., 2023).

For this particular environment, a conceptual model for identifying the various levels, a quick reference table (Table 1) has been prepared below that defines the levels, the components, methods, in addition to identifying the distinct source for each, while identifying, with particular emphasis, the source for behavioral cyber risks.

Table 1: Security Layers in Connected and Autonomous Vehicle Ecosystems

Security Layer	Primary Components	Typical Protection Mechanisms	Common Threat Sources
Physical Layer	Sensors, ECUs, onboard hardware	Tamper resistance, secure boot	Physical access, hardware attacks
Network Layer	V2V, V2I, wireless channels	PKI, certificates, encryption	Message spoofing, replay attacks
Application Layer	Infotainment, vehicle apps	Access control, sandboxing	Malware, vulnerable applications
Cloud & Backend Layer	Navigation services, data storage	Authentication, secure APIs	Data breaches, credential theft
Behavior-Driven Cyber-Risk Layer	User-device interaction, cloud usage, update decisions	User prompts, policies (often weak)	Exploitable user routines, trust misuse

3. The Behavior-Driven Cyber-Risk Layer

The behavior-driven cyber-risk level: This pertains to risks that are not due to weaknesses in cryptographic methods or software bugs but are a result of common user behavior that affects the security level of CAVs negatively (Negash and Yang, 2023).

3.1 Most Common Risk

Various common practices make up such a hidden risk stratification level:

- Ignoring or putting off vehicle software and firmware updates
- Integration of infotainment systems with personal devices that are either unsecured or already compromised
- Shared credentials for all vehicle-related services, mobile applications, and cloud platforms
- Oversharing trip information, location data, and vehicle status via third-party applications
- Accepting unverified applications/permissions

These are usually practiced due to convenience, lack of time, or overreliance on technology. To demonstrate how such behaviors can be interpreted in tangible security threats, Table 2 outlines the principal actions taken by the user, points of interaction, and possible security consequences in the CAV environment.

Table 2: User Behaviors and Their Security Implications in CAV Ecosystems

User Behavior	Interaction Point	Exploited Weakness	Potential Impact
Ignoring software update alerts	Onboard system / mobile app	Unpatched vulnerabilities	Remote exploitation, system compromise
Pairing insecure personal devices	Bluetooth / infotainment	Trusted device abuse	Unauthorized access, data leakage
Reusing credentials	Vehicle apps, cloud platforms	Weak identity separation	Account takeover, tracking
Oversharing trip data	Cloud navigation services	Data exposure	Targeted surveillance, profiling
Accepting unverified applications	Vehicle app ecosystem	Lack of app validation	Malware installation, system manipulation

3.2 Why These Behaviors Matter

CAV security architectures are envisioned to be designed in the belief that the cryptographic trust is sufficient to engender trust (Tu et al., 2025). Nevertheless, when the attack is based on the user behavior, there is an opportunity to circumvent the trust in an indirect manner. For example, if the mobile device is compromised and used in a vehicle, it becomes possible to enter the system as a trusted relay without violating the

cryptographic trust. This layer is particularly dangerous as it stays hidden in the threat space and security analysis.

4. Attack Scenarios Exploiting User Behavior

In spite of the seemingly low-level nature of the risks facing individual users, the group of attackers may utilize these risks systematically to circumvent the conventional CAV security. Through the exploitation of the patterns of behavior of the users or the safe communication pathways between the users and the vehicle, the attackers may obtain false input and gain indirect vehicle access or influence the trust models of the systems. Some of the scenarios accounting for the attack vectors resulting from the patterns of the behavior of the users are presented below.

4.1 Cloud-Based Route and Data Sharing

Many CAV users tend to share their navigation routes and trip history data in cloud services. Attackers who obtain access to such cloud services using either credential reuse attacks or phishing attacks may be able to ascertain the predictable patterns of their driving behavior (Wu et al., 2025). In other advanced attacks, the affected car ecosystem may receive their altered route data. Route data manipulation may occur through several technical attack vectors. For example, attackers may exploit compromised cloud navigation accounts, GPS spoofing techniques, or malicious third-party navigation applications to inject falsified route information. In such cases, altered navigation instructions may redirect vehicles toward unintended routes or manipulate traffic flow. Because many CAV services synchronize route data through cloud platforms and mobile applications, compromised credentials or insecure APIs can allow attackers to modify stored route information that is later downloaded by the vehicle.

4.2 Bluetooth and Infotainment Exploitation

Connecting smartphones to the in-car entertainment systems in a vehicle is also a common phenomenon. Several known Bluetooth attack vectors can exploit these connections. Examples include Bluesnarfing, where attackers gain unauthorized access to data stored on paired devices; BlueBorne, which enables remote code execution through vulnerable Bluetooth implementations; and Man-in-the-Middle attacks, where malicious devices intercept communications between the vehicle and a connected smartphone. These attacks can allow adversaries to access sensitive information, inject malicious commands, or manipulate data exchanged between the vehicle and external services. An attacker, in case the system is compromised, can take advantage of the trust involved in the connection and send malicious information, read credentials, and even tap into information exchanged between the car and the server.

4.3 Spoofed Service Messages and Trust Manipulation

The messages that most users tend to believe come from car services like maintenance notifications and update notifications. The attacker takes advantage of this by sending users spoofed notifications to update malware, provide excessive permissions, or provide sensitive information (Tekkesinoglu et al., 2025). After the creation of this trust through user engagement, the attacker injects false information into the V2V or V2I system chain to indirectly affect decision-making processes.

5. Limitations of Existing User Awareness Approaches

Conventional methods for enhancing awareness and security practices among computer users call for educating and warning users, and then following security guidelines and best practices, and it is expected that a security-aware user will make security-informed choices most of the time. The aforementioned conventional approach is not very effective for a CAV environment, wherein users demand a good deal of automation and functionality with seamless connectivity and very less cognitive efforts while using a system and services (Sevinch, 2024). Frequent reminders for security in high-convenience systems are disregarded because complex warnings are viewed more as impediments than as security solutions. It can cause users to resist and disregard notifications related to security because they do not fully understand their meaning. This is because people believe that secure-by-design safety-critical systems in vehicles are self-protecting and do not necessarily require active user participation for their security.

In addition, knowledge-based approaches are based on the idea that consumers are well-informed about technology risks involved in device pairing, permission handling in applications, data sharing in cloud environments, as well as login methodologies. However, consumers are often left in ignorance about processes that occur in the background, making it impossible to analyze risks. In this manner, consumers might

unknowingly grant permissions that lead to risks in the motor environment. A major drawback of awareness approaches is that they are of a reactive, rather than preventive, nature. These approaches seek to mitigate problems after potentially risky behaviors have taken place, rather than proactively employing system design principles that can pre-emptively prevent the risks from being realized (Butler et al., 2021). This is especially concerning in safety-critical application areas like transportation, which can be directly influenced by human error, not just concerning individual privacy but system-wide issues.

Hence, the applicability of defense mechanisms based on awareness does not scale well in practical CAV deployment, especially with the growing automation of vehicles and integration of CAV systems into everyday life. This emphasizes the importance of having effective remedies related to CAV security, promoting the responsibility of the CAV system itself, apart from humans, regarding reminders, restrictions, or the process of verification. To further clarify these limitations, Table 3 summarizes common awareness-based security strategies, their intended objectives, and the reasons why they are ineffective or impractical within CAV environments. This comparison highlights the gap between traditional user-focused defenses and the operational realities of highly automated vehicle systems.

Table 3: Evaluation of Existing User Awareness Approaches in CAV Environments

Awareness Strategy	Intended Goal	Limitation in CAV Context
Security warnings	Inform users of risk	Often ignored due to automation
User training	Improve decision-making	Not scalable or timely
Policy compliance	Enforce safe behavior	Difficult to monitor
Manual confirmations	Prevent accidental actions	Causes fatigue and frustration
Informational dashboards	Increase transparency	Overwhelming for non-expert users

6. Behavior-Aware Security Framework for CAV Ecosystems

This section presents the **Behavior-Driven Cyber Risk Layer Framework (BDCRL)**, a behavior-aware security architecture that integrates user interaction monitoring with existing CAV security mechanisms.It does not seek to replace cryptographic protections or network-level defenses; rather, the aim is to complement them by considering risk introduced through routine user behaviors and external device interactions. This framework operates within the scope of three interconnected domains: user interaction interfaces, vehicle onboard systems, and cloud services. In this regard, correlating activity across these domains, a system should be able to identify behavior patterns that elevate cyber risk and apply targeted mitigation strategies. Figure 2 provides an overview of this process by illustrating how data flows from user interaction interfaces, onboard vehicle systems, and cloud services into a central behavioral risk analysis component, where risk levels are assessed and translated into adaptive trust adjustments and automated mitigation actions. This visual representation clarifies the cross-layer operation of the framework and highlights how behavior-driven risks are addressed before they impact safety-critical CAV functions.

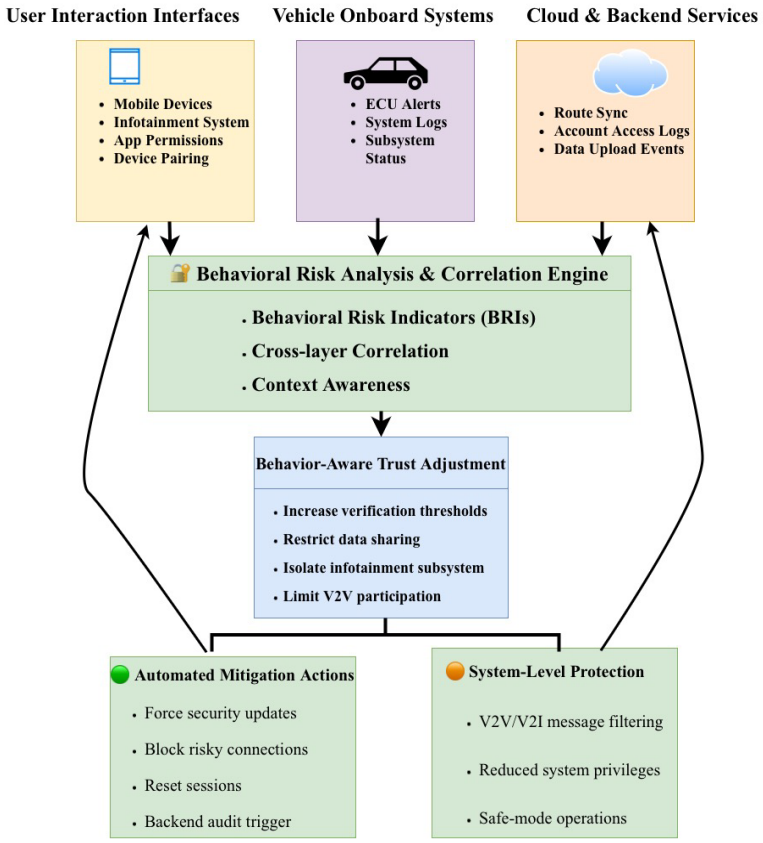

Figure 2: Behavior-Driven Cyber Risk Layer (BDCRL)

6.1 Behavioral Risk Indicators

The first component of the framework defines a set of BRIs that represent actions known to increase the probability of security compromise. These are derived from the common user behaviors that one can find in modern CAV ecosystems, such as:

- Repeated postponement of critical software updates
- Frequent pairing with new or unknown devices
- Installation of third-party applications outside verified ecosystems
- Reuse of authentication credentials across services
- Excessive sharing of location and trip data with external platforms

Each indicator is assigned to a risk weight based on the risk of degrading the overall security of the system. These weights may vary depending on the context in which the vehicle is moving, whether in autonomous mode, interacting with the roadside infrastructure, or in cooperative driving patterns.

6.2 Cross-Layer Risk Correlation

Unlike traditional intrusion detection systems that focus on network traffic or system logs, BDCRL performs cross-layer risk correlation by combining:

- Interface-level interaction logs (e.g., pairing events, permissions granted)
- Vehicle subsystem alerts (e.g., infotainment anomalies, ECU access attempts)
- Cloud-side access and synchronization activity

In correlating these data types, it becomes possible for the system to recognize risk patterns in compounds that individually may be harmless but in combinations suggest something different. In other words, a new device, unusual access to the cloud, and failed log-ins suggest more than simple device failure. By considering the totality of behavioral and system-level indicators, the framework can prioritize patterns that are more likely to represent coordinated or escalating security threats. The reasons behind this are that a strong correlation can facilitate

early identification of attack vectors driven by behavior before they are involved in safety-critical decision-making processes (Almani and Furnell, 2025), such as V2V trust assessment or control of navigation.

6.3 Behavior-Aware Trust Adjustment

The framework introduces a behavior-aware trust adjustment mechanism that influences how vehicle systems evaluate incoming data and external interactions. When elevated behavioral risk is detected, the system can:

- Increase verification thresholds for external messages
- Restrict non-essential data sharing
- Temporarily isolate infotainment and user-connected subsystems
- Limit participation in cooperative V2V decision-making

This dynamic trust adjustment prevents compromised user interfaces from indirectly influencing safety-critical functions. Importantly, trust modification occurs at the system level rather than requiring manual user intervention.

6.4 Automated Mitigation and User Guidance

To minimize reliance on user decision-making, mitigation actions are primarily automated. However, when user input is required, the framework provides *context-aware guidance* rather than generic warnings. For instance, instead of displaying a vague security alert, the system may indicate that recent device connections increase risk during cooperative driving and recommend postponing non-essential connectivity.

Automated responses may include:

- Enforcing immediate critical updates when risk is elevated
- Blocking high-risk device connections
- Resetting compromised authentication sessions
- Triggering backend security audits

This approach balances usability with protection, ensuring that safety is not compromised by delayed or ignored user actions.

6.5 Scenario-Based Validation

For the purpose of testing the feasibility of BDCRL, typical usage scenarios that involve CAVs were examined. These usage scenarios involved cloud-based navigation synchronization, device pairing, as well as service messages. Within these scenarios, the framework was successful in detecting the conditions that pose a higher level of risk prior to making any impact on the trust between V2V or V2I communication. For instance, for route synchronization scenarios, irregular login instances and late updates contributed to trust reduction for external data entry, thereby ensuring that misleading route information does not affect navigation systems. For infotainment pairing scenarios, continuous connectivity attempts from former unknown entities resulted in automatic subsystem isolation, thereby avoiding horizontal access for vehicle services (Ignatious et al., 2023).

6.6 Integration with Existing CAV Security Architectures

BDCRL is designed to be compatible with existing CAV security infrastructures, including certificate-based authentication, secure communication protocols, and backend anomaly detection systems. Behavioral risk scores do not replace cryptographic validation but complement it by adding contextual awareness to trust decisions. The framework uses lightweight behavioral indicators based on existing vehicle logs such as device pairing, update delays, and authentication attempts. Risk analysis can be performed locally within the vehicle, while more complex processing may be offloaded to edge or cloud systems, minimizing computational overhead on safety-critical components. This layered integration supports a more realistic threat model in which trusted vehicles may still act as compromised intermediaries due to unsafe interaction patterns. By recognizing this possibility, CAV systems can make more conservative and informed security decisions ins high-risk operational contexts.

7. Discussion

The behavior-driven cyber-risk layer challenges the assumption that cybersecurity in CAVs can be achieved solely through technical robustness. Even highly secure systems can be undermined by predictable user behaviors that attackers exploit strategically. Recognizing user interaction as a core part of the threat model enables a more realistic assessment of CAV security and highlights the importance of integrating human-centered design

principles into cybersecurity strategies (Xu et al., 2024). While behavioral monitoring can improve cybersecurity in CAV ecosystems, it also raises privacy concerns. To address this, behavioral indicators should minimize or anonymize personally identifiable information whenever possible. Many indicators can be processed locally within the vehicle, reducing the need to transmit user data externally. In addition, compliance with data protection regulations such as GDPR requires transparent data handling and minimal data retention. Therefore, privacy-preserving monitoring is essential for the secure deployment of BDCRL.

The results in this work indicate that cybersecurity concerns for Connected and Autonomous Vehicles cannot be holistically addressed by targeting only technical safeguards such as cryptographic authentication, secure communication protocols, and intrusion detection mechanisms. Inasmuch as such protections are necessary, the findings reveal that mundane user behaviors introduce a parallel vulnerability surface that operates outside the realm of traditional security models.This behavior-driven cyber-risk layer effectively bridges highly secured vehicle subsystems with less regulated personal digital environments, thereby weakening end-to-end system trust.

One of the most significant implications of this work is that many attack paths do not require attackers to compromise core vehicular systems directly (Yousseef et al., 2024). Instead, attackers exploit predictable user routines such as cloud synchronization, smartphone pairing, and reliance on automated services. As shown in Tables 2 and 3, these behaviors can undermine certificate-based trust mechanisms and allow false or manipulated data to propagate into V2V and V2I decision processes. This finding challenges the assumption that cryptographic validity alone is sufficient to ensure operational trust in CAV networks. Another important observation is that behavior-driven risks scale with system convenience. CAV ecosystems are explicitly designed to minimize user effort and maximize automation. The net result of this approach is that meaningful opportunities for effective human oversight are unintentionally reduced. In such environments, traditional cybersecurity awareness strategies become ineffective; users learn to trust system automation and to respond quickly to system prompts without questioning potential security implications. This study shows that real-world CAV usage patterns are poorly aligned with awareness-based defenses; thus, user vigilance is an unreliable mitigation strategy in safety-critical transportation systems (Decian & Jaafar, 2024).

This cybersecurity study further highlights a fundamental disconnect between how responsibilities are assigned for CAV cybersecurity and how these systems are actually used. Current security architectures implicitly place responsibility on users to manage updates, device pairing, and application permissions, despite the fact that users often lack visibility into system dependencies or potential consequences. Treating these behaviors as isolated user errors overlooks the structural role that system design plays in shaping user actions. Therefore, behavior-driven vulnerabilities should be regarded as design-level security issues rather than individual compliance failures. Human-centered cybersecurity practices aim to shift the responsibility for enforcing security from reactive end-user actions to proactive system-level processes. Through the implementation of secure-by-default connectivity, automated verification, and context-aware prompts, the risk of high-risk interactions based on user discretion can be significantly reduced within CAV systems. As summarized in Table 5, these practices complement existing cryptographic protections by targeting vulnerability points at the interfaces where humans interact with automated systems. Furthermore, in a broader context, the behavior-driven cyber-risk layer has significant implications for trust management schemes in vehicular networks. Existing trust models typically assume that malicious behavior originates from malicious vehicles themselves. However, this study demonstrates that legitimate vehicles may unintentionally act as carriers of malicious data or unauthorized access due to compromised user-controlled interfaces. This blurs the distinction between benign and malicious nodes and complicates misbehavior detection mechanisms that rely solely on message-level observations. Consequently, future trust and reputation systems must incorporate behavioral context and device provenance when assessing participant reliability in vehicular networks. Moreover, current regulatory and certification efforts for CAVs place strong emphasis on hardware reliability and software integrity, with limited consideration of security risks arising from user–device interactions. The results of this study indicate that certification frameworks should extend beyond technical compliance to include evaluation of interface design, update enforcement mechanisms, and secure integration with personal devices. Without such measures, certified vehicles may remain vulnerable through their surrounding digital ecosystems.

Finally, although this paper focuses on transportation systems, behavior-driven cyber risks are also evident in other domains, including smart medical devices, industrial IoT, and smart home environments. However, the safety-critical nature of transportation systems magnifies these risks, making CAVs a particularly urgent domain for addressing human–system security interactions. Recognizing human behavior as a contributing factor to

system security is therefore essential not only from a cybersecurity standpoint, but also for ensuring public trust and long-term adoption of autonomous vehicle technologies.

8. Conclusion

In this research paper, the behavior-driven cyber-risk layer in Connected and Autonomous Vehicles has been introduced, and the way in which everyday user behavior leads to hidden, yet highly important, security risks has been explained. By understanding how this user behavior combines with the security features of secure Connected and Autonomous Vehicles, it is evident that the problem of cybersecurity is not just a technological issue, but also a matter of everyday behavior that, at the moment, is not considered highly convenient. Therefore, in order to meet this demand, a set of human-centered approaches, specifically designed for the use of Connected and Autonomous Vehicles, is proposed, and it is necessary to understand that the safety of Connected and Autonomous Vehicles is not just a technological problem, but also a behavior issue.

Ethics Declaration: This study did not involve human participants, personal data, or animal subjects; therefore, ethical approval was not required.

AI Use Declaration: No AI-based tools were used in the preparation of this manuscript.

Cybersecurity in the Era of Quantum Computing and Advanced AI: Emerging Threats and Future Directions

Hisham Alnabulsiyyah and Meteabah Aldawsari
College of Computer and Information Technology, Shaqra University, Saudi Arabia

abo3tb0092@gmail.com

Abstract: Quantum computing and advanced artificial intelligence are beginning to disturb several assumptions on which current cybersecurity practice depends. This paper reviews two related areas of risk: the possibility that cryptographically relevant quantum computers could weaken widely deployed public-key encryption, and the ways in which generative AI and large language models are already changing cyber operations. The analysis finds that quantum risk should not be treated as a distant event only, since sensitive encrypted data can be collected now and decrypted later if suitable quantum capability becomes available. It also finds that advanced AI is already affecting the scale, speed, and credibility of social engineering, reconnaissance, vulnerability analysis, and misinformation. The paper discusses the current state of these threats, outlines plausible future scenarios, and identifies practical defensive priorities, including post-quantum cryptography migration, AI system hardening, red teaming, content authentication, workforce training, and governance. The central argument is that quantum and AI security should be handled as near-term resilience issues, even where their most severe effects may appear later.

Keywords: Cybersecurity, Quantum computing, Post-quantum cryptography, Artificial intelligence, Large language models, Deepfakes

1. Introduction

Cybersecurity has long relied on three assumptions: that certain computations are impractical for attackers, that human users can recognize some forms of deception, and that defenders can observe and respond to compromise before damage becomes systemic. Quantum computing and advanced AI put pressure on all three. Quantum computing threatens the mathematical basis of many public-key systems, while generative AI gives attackers a practical way to produce convincing language, code, audio, and images at scale. These developments do not replace existing cyber risks, instead, they make familiar attacks faster, cheaper, and in some cases harder to recognize.

This paper examines how these technologies reshape the cyber threat landscape and which responses should be prioritized. It focuses on two questions. First, how could quantum computing affect encryption, signatures, and digital trust? Second, how could advanced AI and large language models introduce new vulnerabilities or strengthen existing attacker capabilities? The discussion draws on recent academic, government, and industry sources, with emphasis on realistic security implications rather than speculative forecasts. The paper does not attempt to predict an exact date for a cryptographically relevant quantum computer. That date remains uncertain. The more useful question is whether the direction of risk already justifies defensive action.

The argument advanced here is that the security community is already in a transition period. Quantum computers are not currently breaking strong, real-world public-key encryption, but migration to quantum-resistant systems will be slow and operationally difficult. Current AI systems are also not fully autonomous attackers, but they already improve phishing, impersonation, malware support, and vulnerability analysis. Waiting for either threat to mature before preparing would leave organizations with limited time to respond. A more defensible approach is to build cryptographic agility, secure AI development practices, and governance controls while the risks are still manageable.

2. Quantum Computing and the Cryptographic Risk

The most widely discussed cybersecurity implication of quantum computing is its effect on public-key cryptography. Systems such as RSA, Diffie-Hellman, and elliptic-curve cryptography depend on mathematical problems that are difficult for classical computers, including integer factorization and discrete logarithms. A sufficiently powerful quantum computer running Shor's algorithm could solve these problems efficiently, making many current public-key schemes unsafe [1], [2]. The effect would reach far beyond encrypted messaging. Secure web browsing, virtual private networks, software updates, digital signatures, identity systems, and parts of financial infrastructure all rely on these mechanisms.

The more immediate concern is not only future decryption. The strategy often described as harvest now, decrypt later changes the timeline. An adversary can collect encrypted traffic or stored encrypted records

today and preserve them until quantum decryption becomes practical. Data with long confidentiality value, such as government communications, medical records, intellectual property, legal material, and financial information, may therefore be exposed before the technical ability to decrypt it exists [3]. This is why organizations that protect long-lived sensitive data cannot wait for a public quantum breakthrough before planning their transition.

Current quantum hardware still faces major limits, including noise, error rates, and the difficulty of scaling fault-tolerant systems. Publicly known systems do not yet have the stable, error-corrected capability required to break large commercial cryptographic deployments. However, progress in algorithms, error correction, and hardware engineering has reduced confidence in the assumption that the risk is safely remote. NIST and related agencies have warned that preparation should begin before the threat becomes operational [1], [3]. The practical challenge is that cryptographic migration is not a single software patch. It requires finding where cryptography is used, replacing vulnerable algorithms, testing interoperability, updating certificates and protocols, managing legacy devices, and coordinating with vendors.

Post-quantum cryptography is the main defensive pathway. These algorithms are designed to resist both classical and quantum attacks by relying on mathematical assumptions such as structured lattices, hash-based signatures, and code-based problems. NIST's standardization process has produced finalized post-quantum encryption and signature standards, which gives organizations a clearer basis for planning [1]. The transition should be managed through cryptographic agility: systems should be designed so that algorithms can be replaced without redesigning the full architecture. That matters because post-quantum algorithms are newer than the schemes they will replace, and implementation guidance will continue to mature. The most sensitive and long-lived assets should be addressed first.

Quantum risk also affects trust models beyond confidentiality. Digital signatures verify software updates, contracts, identity credentials, and blockchain transactions. If widely used signature schemes become vulnerable, attackers could impersonate trusted parties or distribute malicious updates that appear legitimate. Symmetric cryptography is less exposed, but it is not unaffected, Grover's algorithm reduces the effective security strength of symmetric keys, which means key sizes and hash functions should also be reviewed. These issues do not make current systems obsolete overnight, but they do require a systematic inventory and staged upgrade plan.

3. Advanced AI and Large Language Model Security Risks

Compared with quantum computing, advanced AI is already operationally relevant because usable tools are widely available now. Generative models can draft convincing emails, summarize stolen documents, translate scams, imitate a professional tone, generate code, and support research on targets. Large language models also create new attack surfaces when they are embedded into customer service tools, coding assistants, search systems, document analysis tools, and autonomous agents. The main security issue is not that every model output is dangerous, but that models can be connected to sensitive data and actions without the same predictable boundaries as conventional software.

Prompt injection is one of the clearest examples. In a prompt injection attack, malicious instructions are placed inside user input, a document, a web page, or another data source that the AI system processes. The model may then follow those instructions rather than the developer's intended policy. In practice, an attacker could try to cause an AI assistant to disclose sensitive content, ignore access rules, send data externally, or take an unsafe action through a connected tool [4], [5]. The risk grows when an LLM has access to email, files, databases, or internal applications, because the model may not reliably separate trusted system instructions from untrusted content that merely looks like an instruction.

Other AI-specific risks include jailbreaking, adversarial examples, data poisoning, and model backdoors. Jailbreaking attempts to bypass restrictions and obtain outputs that the system is meant to block. Adversarial examples manipulate inputs so that a model behaves incorrectly. Data poisoning targets training or fine-tuning data, while backdoors remain hidden until a specific trigger appears. These problems are difficult to manage because modern models are complex, probabilistic, and not fully interpretable. A system can perform well in ordinary testing and still fail when placed under adversarial pressure.

AI also changes the economics of conventional cybercrime. Phishing is the most visible case. Older phishing campaigns often contained weak grammar, generic wording, or obvious inconsistencies. Generative AI allows attackers to produce personalized messages that sound professional and can be adapted quickly after failure. The FBI has warned that criminals are using AI to increase the speed, scale, and believability of fraud and social

engineering [6]. The same pattern applies beyond email, including text messages, voice calls, fake job offers, business email compromise, and customer support fraud.

Deepfakes extend the same problem into voice and video. AI-generated media can imitate executives, relatives, public figures, or colleagues. In a corporate setting, a convincing fake voice call can support payment fraud or credential theft. In a public setting, fake video or audio can spread misinformation, damage reputations, or create short-term panic before verification catches up. Detection tools are useful, but they are not enough on their own, since attackers can improve generation quality and exploit situations where people are under time pressure.

AI may also accelerate technical attacks. Models can assist with code analysis, vulnerability research, exploit adaptation, and the interpretation of technical documentation. They are unlikely to replace expert attackers in the near term, but they can lower the skill required for some tasks and increase productivity for experienced teams. A threat actor can use AI to generate reconnaissance scripts, analyze error messages, rewrite simple malware, or summarize the configuration of a target technology. The expected defensive challenge is therefore greater volume, faster iteration, and more convincing social engineering rather than a single new form of attack.

4. Combined Threat Landscape and Future Scenarios

Quantum and AI risks are often discussed separately, but operationally they are part of a broader shift. AI gives attackers automation and persuasion advantages now, while quantum computing threatens the cryptographic layer that supports digital trust over the longer term. The combined effect is a security environment in which attackers may become better at gaining access today and, in the future, better able to exploit information that was previously protected by older cryptography.

One plausible scenario begins with data harvesting. An attacker collects encrypted records from a high-value organization and stores them. AI-assisted tools are then used to identify employees, suppliers, and business processes, making credential theft or supplier impersonation more credible. Once inside a network, the attacker searches for stored encrypted databases, certificate material, and long-term secrets. If quantum decryption later becomes practical, data taken years earlier may become readable. This scenario links a present compromise to a future cryptographic failure and shows why the two risks should be planned together.

A second scenario involves AI-enabled exploitation of AI systems themselves. Organizations are increasingly deploying chatbots and assistants into workflows that can access documents, calendars, customer records, or code repositories. If these systems lack strong boundaries, indirect prompt injection can become a route from an untrusted document to a sensitive action. A malicious document, for example, may instruct an assistant to summarize confidential files or leak selected information through an external request. The model does not need to be malicious, it only needs to become the mechanism through which the attack is carried out.

Critical infrastructure raises the stakes further. AI systems may support monitoring, optimization, and decision-making in energy, healthcare, transport, and finance. At the same time, long-lived infrastructure communications may require quantum-safe protection. The risks are not limited to confidentiality. Integrity failures can be equally serious: a manipulated AI recommendation, a forged signature, or a compromised update process could cause operators to trust false information.

It is also important not to frame either technology only as a threat. AI can improve anomaly detection, malware triage, incident response, and vulnerability management. Quantum technologies may eventually support stronger forms of key distribution or random number generation in specialized settings. These benefits will only be useful if deployment is disciplined. Without clear controls, validation, and accountability, the same capabilities can increase complexity and enlarge the attack surface.

5. Mitigation Strategies

For quantum risk, the practical starting point is an inventory. Organizations need to know where public-key algorithms are used, which systems protect long-lived data, and which vendors control cryptographic components. The inventory should include certificates, VPNs, web services, email encryption, identity systems, code-signing processes, embedded devices, and backup systems. After that, assets should be classified by urgency. Systems protecting sensitive data for many years should move earlier in the migration plan than systems with short-lived confidentiality needs.

Migration to post-quantum cryptography should be staged and tested. Hybrid approaches may be useful during the transition because they combine classical and post-quantum mechanisms while the newer schemes mature in operational use. Procurement requirements should also be updated so vendors demonstrate post-quantum support and cryptographic agility. This is especially important for devices and platforms with long service lives, since they may still be deployed when quantum threats become more practical.

For AI security, LLM applications should be treated as software systems with unusual failure modes, not as simple user interfaces. Access control should be enforced outside the model. The model should not be the only authority deciding whether a user may view, send, or modify information. Sensitive actions should rely on deterministic policy checks, logging, and human confirmation where appropriate. External documents, websites, and emails should be treated as untrusted inputs even when processed by an internal AI assistant.

Prompt injection defenses need layers. Separating system instructions from user content is useful, but it is not sufficient by itself. Applications should limit which tools the model can call, restrict data access to the minimum necessary, sanitize or transform untrusted inputs, and monitor outputs for suspicious behavior. Red teaming should be part of the deployment lifecycle. AI systems should be tested with adversarial prompts, malicious documents, indirect prompt injection examples, jailbreak attempts, and realistic abuse cases before and after release.

Social engineering controls also need to be updated. Employees should be trained on AI-generated phishing and deepfakes, but training cannot be the only control. High-risk actions such as payments, credential resets, sensitive data exports, or urgent executive requests should require independent verification through trusted channels. Phishing-resistant multi-factor authentication, domain authentication, and transaction approval workflows remain necessary because awareness alone is unreliable when people are under pressure.

Content authenticity is another defensive layer. Watermarking, provenance metadata, and cryptographic signing of legitimate media can help users and institutions verify whether content came from a trusted source. These methods will not stop all deception, but they can reduce uncertainty in high-value communications. Incident response plans should also include deepfake procedures, including rapid verification, public communication, and escalation paths.

Governance connects these technical controls to responsibility. AI systems used in security-sensitive contexts should have documented owners, risk assessments, logging, model update procedures, and clear rules for human oversight. Quantum readiness should be included in enterprise risk management rather than left as a research topic for specialists. Organizations that prepare early will have more control over cost, compatibility, and timing than those that wait for a crisis.

6. Future Research Directions

A first research priority is practical migration engineering for post-quantum cryptography. Standards are only the starting point. Researchers and practitioners need evidence about performance, interoperability, certificate sizes, implementation mistakes, and secure deployment patterns in real systems. Constrained devices, industrial systems, and legacy infrastructure deserve particular attention because many cannot be upgraded quickly or cheaply.

A second priority is AI system evaluation. Current benchmarks do not fully capture security behavior in real deployments, especially when models are connected to tools and private data. Future evaluations should test indirect prompt injection, multi-step attacks, tool misuse, data leakage, model behavior under conflicting instructions, and resistance to adaptive jailbreaks. The goal is not to prove that a model is perfectly safe, which is unrealistic, but to measure risk clearly enough to support deployment decisions.

A third priority is interpretability and verification. Security teams need better ways to understand why a model takes a certain action and whether hidden instructions or poisoned data influenced it. This is especially important for autonomous agents that plan across multiple steps. If an AI system can read files, call APIs, and make decisions, defenders need audit trails and policy enforcement that are stronger than ordinary chat logs.

A fourth priority is human-centered security. AI-generated deception targets trust, urgency, and authority. Research should examine which verification methods work under realistic pressure and which training designs actually change behavior. Technical systems should support people rather than assume that every individual will detect every fake. For example, payment systems can require independent confirmation by design instead of relying on an employee to notice a suspicious voice call.

Finally, cross-disciplinary education is needed. Cybersecurity professionals will need enough knowledge of AI and quantum computing to ask the right questions, while AI and quantum specialists will need enough security knowledge to understand misuse and deployment risk. Universities, professional programs, and industry training should reflect this shift. The future security workforce will need both technical specialization and the ability to work across disciplines.

7. Current State and Future Outlook

The current quantum threat is best described as a preparation problem before the main impact. Today's quantum computers are not able to break large public-key systems used across ordinary digital infrastructure. The risk is therefore not an immediate mass decryption event. The risk is that migration will be long, uneven, and dependent on many vendors and protocols. Organizations that begin with inventory and staged testing now can move deliberately. Organizations that wait for a major breakthrough may face rushed migration, compatibility failures, and continued exposure of archived data.

AI risk is at a different stage. AI-enabled attacks are already visible because widely available tools can produce text, images, voice, and code. The most realistic near-term expectation is not a fully autonomous AI hacker, but a steady increase in the efficiency of human-led attacks. This matters because cybersecurity teams are already overloaded by alert volume, patching demands, and social engineering. AI adds pressure to the same weak points.

Over the next five to ten years, the defensive gap will likely depend less on whether organizations have heard about these risks and more on whether they convert awareness into engineering change. Quantum readiness will require procurement rules, protocol updates, and support from cloud providers, software vendors, and device manufacturers. AI readiness will require secure design patterns for AI applications, stronger identity verification, and incident response for synthetic media. Organizations that treat these areas as ordinary cyber hygiene will reduce disruption. Those that treat them as distant research topics may find that their controls age faster than expected.

8. Conclusion

Quantum computing and advanced AI are reshaping cybersecurity in different but connected ways. Quantum computing threatens public-key cryptography and makes post-quantum migration necessary, especially for data that must remain confidential for many years. Advanced AI is already increasing the quality and scale of cyber threats, particularly in phishing, impersonation, vulnerability support, and exploitation of AI-enabled systems. Both technologies create risks that traditional controls alone cannot fully address.

The most important issue is timing. Waiting for quantum computers to break encryption or for AI attacks to become fully automated would be a strategic error. Post-quantum migration requires years of inventory, testing, vendor coordination, and operational change. AI security requires stronger access boundaries, red teaming, secure development practices, and governance. Defenders still have a window to prepare, but that window will narrow as the technologies mature.

A practical cybersecurity strategy for the next decade should therefore be both quantum-aware and AI-aware. It should protect long-lived data, build cryptographic agility, secure AI systems as part of the software supply chain, verify high-risk communications, and train professionals who can work across these domains. The aim is not to resist technological progress, but to keep digital infrastructure trustworthy as the underlying technology changes.

Ethics Statement: This paper is a literature-based cybersecurity study and does not involve human participants, animal subjects, clinical data, personal data collection, experiments on live systems, unauthorized access, malware deployment or active testing against third-party infrastructure. The discussion of threats is presented at a high level for academic and defensive purposes. The paper avoids operational instructions that would enable cyber abuse and is intended to support responsible security planning, risk awareness and future research.

AI Use Statement: AI-assisted editing tools were used in a limited way during revision to support grammar, clarity, formatting, and consistency checks. The authors reviewed all arguments, verified the cited sources, and accept full responsibility for the accuracy, originality, and integrity of the final manuscript. No AI tool was used as an independent source of authority for the technical claims in this paper.

Audio Deepfake Generation and Detection using Deep Learning for Digital Forensic Analysis

Mahra Alnaqbi and Richard Ikuesan
Zayed University, Abu Dhabi, UAE

Mahar.Alnaqbi@gmail.com
Richard.Ikuesan@zu.ac.ae

Abstract: Deepfake audio technology has developed rapidly and now poses serious risks in cybersecurity and digital forensic analysis. Synthetic speech can imitate authentic human voices, which makes manual and automated detection difficult. This study investigates deep learning-based methods for detecting audio deepfakes generated using modern speech synthesis and voice conversion techniques. The work focuses on both generation and detection in order to understand how different deepfake methods affect detection performance. The study employs multiple audio generation models, including Coqui TTS, GAN, RealNVP, VAE, and WaveNet, to generate realistic speech. Several deep learning detection models are evaluated, including CNN, LSTM, BiLSTM, CNN-LSTM, CNN-BiLSTM, conditional GAN, and hybrid architectures that combine convolutional and recurrent layers. Three datasets are used for training and evaluation. These include a self-generated deepfake dataset, a public Kaggle deepfake dataset, and the ASVspoof 2021 deepfake dataset. This combination allows evaluation under both controlled and real-world conditions. Experimental results indicate apparent performance differences among model types. Simple sequential models, such as LSTM and BiLSTM, perform poorly when deepfake audio exhibits strong naturalistic characteristics. This issue is most evident in Coqui TTS-generated audio, which is difficult to detect because of its natural tone and smooth articulation. In comparison, hybrid models that combine convolutional and recurrent learning consistently achieve higher accuracy and stronger generalization across datasets. The Hybrid cGAN with BiLSTM achieves near-perfect detection performance and exhibits stable performance across cross-validation folds and on independent test data. These results confirm that combining spatial and temporal feature learning improves robustness against advanced deepfake attacks. The study also introduces AudioForenX, an interactive forensic tool that integrates the best-performing models. AudioForenX enables real-time analysis, waveform visualization, and classification of audio samples as authentic or synthetic. The findings confirm that hybrid deep learning architectures provide reliable, balanced, and highly accurate detection of synthetic audio. This study contributes practical insights for digital forensics and supports the development of effective tools to counter audio deepfake threats.

Keywords: Audio deepfake detection, Bidirectional LSTM, Conditional GAN, Convolutional neural network, Deep learning, Speech synthesis

1. Introduction

Audio deepfakes now represent a critical security threat in modern communication due to their ability to imitate authentic human voices with high accuracy. They are already being used for fraud, impersonation, misinformation, and cyberattacks, and current manual or human judgment is no longer sufficiently reliable to detect them. This creates a significant risk in environments where voice is used for authentication, evidence, or identity verification. This study begins with this core challenge and investigates how deep learning (DL) can reliably support the forensic need to distinguish real human speech from synthetic speech.

Audio deepfake technology builds on DL models to create synthetic speech that is almost indistinguishable from real human speech. These models can manipulate or generate voice recordings that replicate the tone, pitch, rhythm, and emotion of a real person. Speech synthesis and voice conversion now allow the cloning of vocal identity with very high precision. The term deepfake joins deep learning and fake to show the technology that enables this transformation (McGettigan et al., 2024). Audio deepfakes, like many other deepfakes, were initially used for lawful purposes. They made a personalized speech for people with speech disorders as well as made the virtual assistants such as Siri and Alexa more natural. Unfortunately, the same technology is being used maliciously today. Such intelligence is exploited by criminals for identity theft, impersonation, and misinformation campaigns. It has raised concerns among security and media professionals, who are struggling to detect fabricated audio (Akhtar et al., 2024; Liu et al., 2024).

Audio deepfakes have become more and more convincing due to the fast evolution of DL models. Early robotic speech was robotic and unnatural-sounding. WaveNet and Tacotron generate speech so realistically that they almost perfectly imitate tone, pitch, and emotion (Li et al., 2025). The level of realism is so high that professionals trained to detect such audio manipulation face difficulty without advanced tools. The increasing use of audio deepfakes in cyberattacks underscores the need for robust detection mechanisms (Alali & Theodorakopoulos, 2024). In the previous decade, the development of audio deepfake technology has advanced significantly. Initially, speech synthesis used feedback based on basic signal-processing techniques to

produce synthetic speech. The early systems were successful only in a limited sense: they replicated natural human speech. DL changed many things. With the arrival of generative adversarial networks (GANs) and recurrent neural networks (RNNs), it became possible to generate highly realistic speech (Alshehri et al., 2024; Choi et al., 2024). Using publicly available software such as VoiceClone and Resemble AI, even non-experts can create realistic synthetic voices (Mirsky & Lee, 2021). As a result, audio-based threats have risen in number due to this ease of access.

One of the most important milestones in this evolution is the development of neural text-to-speech (TTS) models. Unlike traditional TTS systems, neural TTS models learn complex patterns in human speech from data (Li et al., 2024). In fact, they do not just record what people say; they also record how that person expresses their emotions. With advances in this technology, synthetic audio is becoming more realistic, and detecting it is becoming more difficult (Wang et al., 2024). While deepfake generation models have improved rapidly, equally strong detection models have not developed as rapidly. Many existing methods fail when tested against novel deepfake types or voices generated by advanced speech synthesis techniques. This creates a clear research gap for detection models that are accurate, adaptable, and capable of operating under real forensic constraints.

Digital forensics plays an important role in the creation, storage, and alteration of digital evidence. It provides investigators with a defined process for examining data in a careful and controlled manner. It also ensures that the evidence is reliable when used for legal or security decisions. The rapid growth of audio deepfakes has made this forensic task more difficult. Modern deepfake models do not leave such visible clues. They replicate human tone, pitch, and time with great accuracy. Signal transformations, including the Wavelet Transform (WT), Constant-Q Transform (CQT), and Short-Time Fourier Transform (STFT), can be used in digital forensics to convert audio into visual patterns that reveal important details (Pham et al., 2024). Existing studies explain why the field of digital forensics is now under new pressure. They demonstrate that audio evidence is no longer readily credible. They also indicate that deepfake audio continues to improve rapidly.

This study follows this direction by examining the impact of deepfake audio on speech structure. It also develops detection methods that support precise and reliable forensic decisions. These forensic requirements directly motivate the study and guide the development of detection models and the final forensic tool. The study aims to develop and evaluate DL-based methods for generating and detecting audio deepfakes for use in digital forensic analysis. It also aims to build a practical tool for real-time verification of human speech authenticity. The study focuses on improving accuracy, generalization, and forensic reliability in realistic digital environments. The study sets the following objectives: to study and organize the state-of-the-art methods in audio deepfake creation and detection, to examine different DL models and identify the most suitable method for detecting audio deepfakes, to build a dataset of real and fake audio samples for forensic testing, and to develop a forensic analysis tool that supports the investigation and reporting of audio deepfakes.

2. Literature Review

Many studies focus on how audio deepfakes work and how to prevent them. Early work focused on speech synthesis and voice conversion. Later, DL models changed all this. Some studies are about the risks, and others focus on fake voice detection by ML. Detection is difficult because deepfake technology continues to improve. This section reviews key studies on audio deepfake generation and detection.

Li et al. (2025) developed SONAR, a benchmark framework for detecting AI-synthesized audio across various TTS and Voice Conversion (VC) models. As this Realistic AI Speech technology has advanced, distinguishing the authentic voice of a human from deepfakes has become challenging because current detection methods generalize poorly. SONAR fills this gap by evaluating detection systems on a novel dataset from nine varied audio synthesis platforms. They demonstrate that foundation models generalize better than traditional systems due to their larger scale and richer pretraining data. Xie et al. (2024) present FakeSound, a dataset designed explicitly for deepfake general audio detection. FakeSound is a strong benchmark for evaluating deepfake detection models. A general-purpose audio pre-trained framework is proposed, which outperforms state-of-the-art deepfake speech detectors and human testers. Alali and Theodorakopoulos (2024) present a detailed review of the methods for generating and detecting TTS, VC, and partially fake audio. TTS and VC deepfake detection models are very accurate and robust to unseen data. However, partially synthetic audio, which consists of a mixture of real and synthetic speech, remains a challenging problem. The authors discuss key characteristics of publicly available datasets and highlight the growing importance of detecting partially synthetic audio.

Zhang et al. (2024) contributed to the increasing threat of deepfake audio by their DeepFakeVox-HQ dataset, which comprises 1.3 million samples, including 270,000 high-quality deepfakes. They introduced Frequency-Selective Adversarial Training, which focuses on high-frequency components that attackers often use to hide. Results show improvement to model performance in difficult situations and validate the importance of using robust and realistic datasets for deepfake detection. Dagar and Vishwakarma (2022) studied the use of GANs and Variational Autoencoders in the generation of audio deepfakes. They focus on how rapidly these generative models have grown and discuss the modern methods, datasets, and architectures. The challenges and limitations of the technology are also discussed, as are future directions for improved security and detection.

Sharma et al. (2024) propose a multimodal deepfake detection method that leverages video and audio data. They use DL to extract important features from both modalities. In audio media, Convolutional Neural Networks (CNNs) are used to detect patterns of fake content, typically using mel-spectrograms. Their model improves the accuracy and precision by combining the audio and video data. Wani et al. (2024) used CNN and Bidirectional Long Short-Term Memory (BiLSTM) to analyze multiple audio features, including CQT, Constant-Q Cepstral Coefficients (CQCC), mel-spectrograms, and Mel Frequency Cepstral Coefficients (MFCCs). CNN layers created multi-dimensional feature representations, and BiLSTM captured temporal patterns. The model achieved high accuracy on ASVSpoof 2019 and FoR datasets. Alshehri et al. (2024) presented Sonic Sleuth, an Artificial Intelligence (AI) model for detecting audio deepfakes. Sonic Sleuth has an accuracy of 98.27%. The model performs well even under noisy conditions and supports multiple languages.

Deepfake forensics focuses on how investigators study, verify, and explain audio evidence reliably. The field assists in legal work, where the truth of the recording must be determined before it is used in a case. Several studies aim to address this gap by presenting models, tools, and workflows for investigating both speech and synthetic speech. The reviewed studies show that the DL models have been the most effective tools in identifying audio deepfakes. The CNNs, BiLSTMs, and hybrid models achieve good performance by learning spectral and temporal features. Models that incorporate augmentation, privacy protection, or multimodal inputs also yield more accurate results by processing more complex patterns (Sharma et al., 2024). Extensive datasets, such as DeepFakeVox HQ and FakeSound, support these models by providing a wide range of high-quality samples (Zhang et al., 2024; Xie et al., 2024).

However, many gaps remain. Most detection models struggle when tested on types of deepfakes they have never encountered. New TTS and VC systems generate voices that are more natural than those in older datasets, which limits generalization. These gaps indicate the need for further research. There is a clear need for models that can detect deepfakes across different synthesis methods, operate on noisy data, explain their decisions, and support forensic reporting.

3. Methodology

This section describes how audio deepfakes are generated and detected. It explains the dataset preparation, feature extraction, deepfake generation techniques, and DL-based detection models used in the study. Figure 1 demonstrates the operational framework employed in the study. The study selected deepfake generation and detection algorithms following a detailed exploratory process. This explains that the selection was purposeful and guided by investigation.

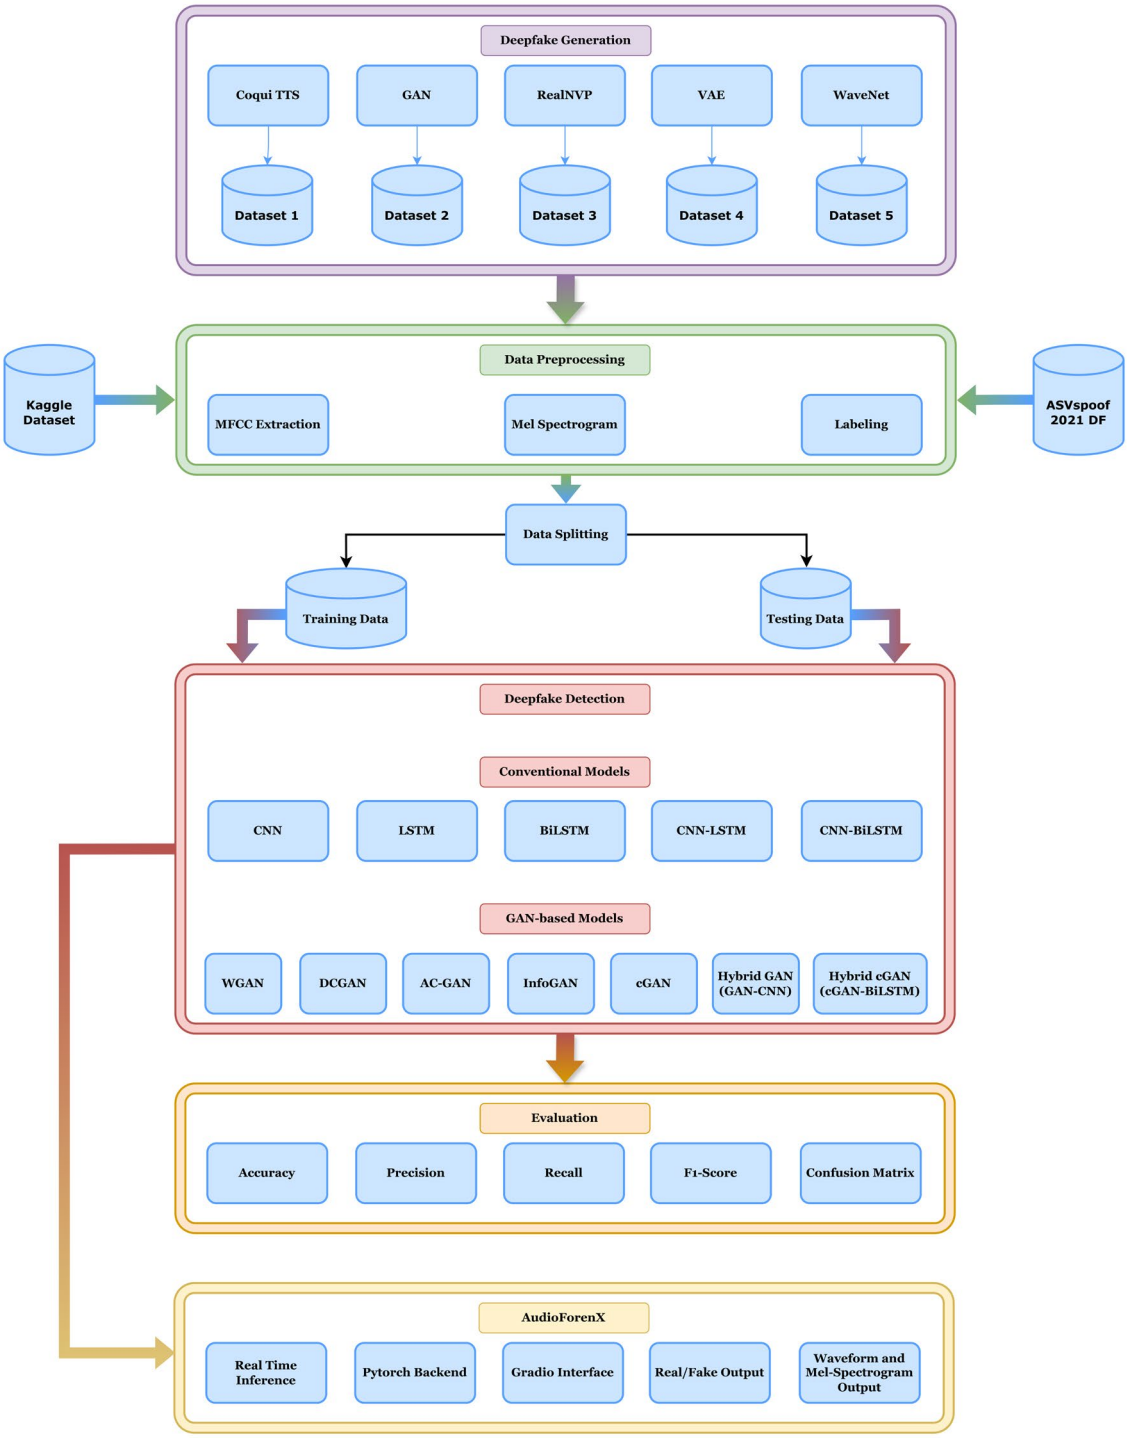

Figure 1: Methodology Overview

3.1 Dataset Generation and Preparation

Real audio samples were generated based on the Coqui TTS model and other methods. The Coqui TTS model was used to synthesize human-like speech from predefined text prompts. A variety of sentences were used to produce a variety of speech recordings. These clips retained their natural tone, pitch, and rhythm, which are pretty similar to human speech. All generated real audio samples were saved in a separate dataset folder. Each file was saved in .wav format with a standardized sampling rate. The dataset was designed to be consistent to enable high-quality speech synthesis.

Fake audio samples were produced by altering the real speech using DL models. Multiple techniques were employed to make the synthesized audio natural while retaining some of the variables that distinguish it from

actual speech. The modification techniques included changes to the speech waveform's frequency, slowing or speeding the audio without altering pitch, and the introduction of background noise. In addition, deep generative models were also used to generate fake audio datasets. Each technique introduced different variations. These techniques generated diverse datasets, resulting in robust detection. The total number of audio samples per technique was 10,000, comprising 5,000 real and 5,000 synthetic samples.

3.2 Public Dataset Collection

Two public datasets were used. The Kaggle "Deepfake Detection in Audio" dataset contains labelled real and fake audio samples and supports supervised classification (Sizakele, 2024). The ASVspoof 2021 Speech Deepfake dataset contains real and synthetic speech generated under realistic conditions and was used to test robustness and generalization (Skenospeniel, 2021).

3.3 Feature Extraction and Preprocessing

In order to effectively train DL models, it is essential to transform raw audio data into meaningful representations. The feature extraction technique has been used to extract essential characteristics of speech. MFCCs were extracted from each audio sample. MFCCs model how humans perceive sound and have been widely used in speech recognition and deepfake detection. Each audio file is converted into a 40-dimensional MFCC vector. This conversion preserves key features while reducing noise and redundancy. Mel spectrograms are visual representations of sound that show the evolution of frequency components over time. CNNs use spatial structures to detect deepfake patterns through spectrograms. To improve model robustness, the spectrograms were augmented with noise. To prevent overfitting and improve generalization, factual distortions were simulated by adding Gaussian noise.

All audio files from Kaggle and ASVspoof 2021 datasets were resampled to 16 kHz and converted to single-channel waveforms. Each audio clip was padded or trimmed to four seconds. Every waveform was converted to a mel-spectrogram using the short-time Fourier transform. A total of 64 mel-frequency bins were extracted. The mel-spectrograms were normalized to the range -1 to 1. Time masking and frequency masking were applied to enhance generalization.

3.4 Deepfake Audio Generation Techniques

Powerful DL techniques are used in the generation of audio deepfakes. This study employed five generative models: Coqui TTS, GAN, Real-Valued Non-Volume-Preserving (RealNVP), Variational Autoencoder (VAE), and WaveNet. Coqui TTS generated speech from written text. It produced audio that sounded human-like, capturing tone, pitch, and rhythm. GANs used a generator and a discriminator in adversarial training to produce synthetic audio. The generator learned speech patterns from real data and refined its output through feedback. RealNVP generated deepfake audio by learning an invertible transformation between real and fake distributions. VAE learned latent representations of real speech and reconstructed synthetic samples. WaveNet generated speech sample by sample and captured fine temporal and spectral details of human voices. Each generation method produced datasets containing 5,000 real and 5,000 fake samples. These balanced datasets enabled reliable training and evaluation.

3.5 Deepfake Detection Models

Detecting deepfake audio requires powerful DL models. The study used CNN, Long Short-Term Memory (LSTM), BiLSTM, CNN-LSTM, CNN-BiLSTM,, Wasserstein GAN (WGAN), Deep Convolutional GAN (DCGAN), Auxiliary Classifier GAN (AC-GAN), Information Maximizing GAN (InfoGAN), Conditional GAN (cGAN), Hybrid GAN, and Hybrid cGAN with Bi-LSTM. CNNs extracted spatial features from spectrograms. LSTMs captured temporal dependencies. BiLSTMs analyzed sequences in both forward and backward directions. Hybrid CNN-LSTM and CNN-BiLSTM models combined spatial and temporal learning. GAN-based models learned discriminative patterns through adversarial training. Five-fold cross-validation was applied to ensure reliable evaluation.

3.6 AudioForenX Tool Development

The study developed an end-to-end deepfake detection tool called AudioForenX. The system uses a Python backend implemented in PyTorch and an interactive Gradio interface. It loads trained cGAN, Hybrid GAN-CNN, and Hybrid cGAN-BiLSTM models using original files. Uploaded audio is normalized, resampled, padded, and converted to mel-spectrograms using the same pipeline as the training process. Predictions are displayed

along with waveform and spectrogram visualizations. The tool supports CPU- and GPU-based execution and does not store user audio, thereby ensuring privacy.

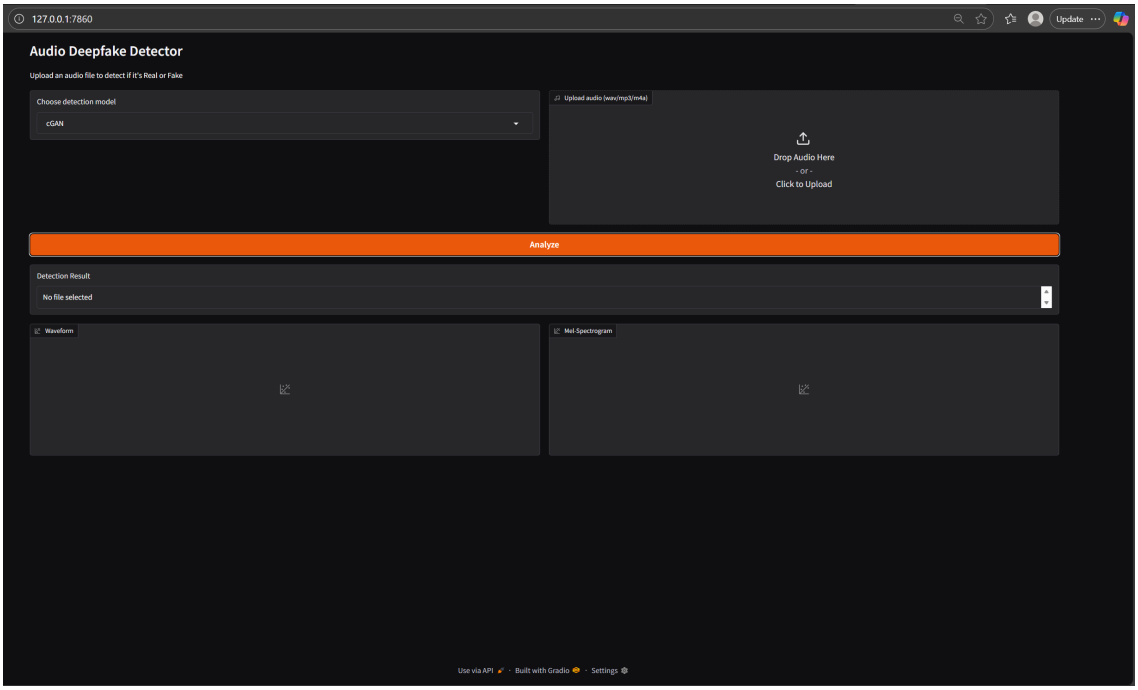

Figure 2: AudioForenX Interface

4. Results and Analysis

This section presents the results of all deepfake detection models on the generated and collected audio. These results explain the generation methods' ability to produce high-quality deepfakes and demonstrate how well the detection models identify them. The developed tool is also evaluated for accuracy and interpretability to clarify its forensic value.

4.1 Results on Generated Deepfake Data

Coqui TTS-generated data posed a challenge for all detection models. This dataset included real audio and high-quality synthetic audio that were difficult to separate. CNN achieved the best performance across all metrics, achieving 93% accuracy. However, LSTM and BiLSTM models struggled to detect deepfakes, achieving less than 90% accuracy. This indicates that simple sequential models cannot accurately detect deepfakes in Coqui-generated data. Coqui TTS-generated data was the most difficult to detect. Some models misclassified fake samples. This makes the Coqui TTS technique more efficient than others. The dataset generated with the GAN model contained high-quality synthetic samples. All detection models achieved perfect classification on GAN-generated data. The perfect accuracy observed on GAN-generated data does not indicate that the models have unlimited generalization ability; instead, the GAN audio contained clear spectral artifacts that made the samples easier to detect. The RealNVP model produced high-quality audio, and all detection models achieved almost perfect classification. The VAE model also produced high-quality audio, and most models achieved perfect classification, although CNN had minor misclassifications. The WaveNet model produced deepfake audio that all models perfectly detected. Hybrid models, CNN-LSTM and CNN-BiLSTM, performed best on all datasets.

Table 1: Results on Generated Deepfake Data

Dataset	Best Model(s)	Best Accuracy	Key Notes
Coqui TTS	CNN	0.93	High-quality deepfakes. Sequential models struggled.
GAN	All models	1.00	Clear patterns. Perfect detection.
RealNVP	All models	1.00	All models detected samples perfectly.
VAE	Most models	1.00	CNN had minor errors. Others perfect.
WaveNet	All models	1.00	Perfect detection.

4.2 Results on Kaggle Deepfake Data

The Kaggle deepfake dataset contains real and synthetic audio, which serves as the basis for deepfake classification. The WGAN achieved an overall accuracy of 60.23%. The results show that the model was biased towards the real class. The DCGAN achieved moderate performance but misclassified many fake samples. The AC-GAN achieved lower accuracy and performed better at detecting fakes than at detecting real data. The InfoGAN achieved moderate accuracy but exhibited a bias toward real audio. The cGAN achieved perfect performance across all validation folds. The model had an accuracy, precision, recall, and f1-score of 1.00. The Hybrid GAN with CNN achieved high stability and near-perfect performance. The Hybrid cGAN with a Bi-LSTM achieved near-perfect accuracy and strong generalization. These results show that hybrid models are more reliable for deepfake detection.

Table 2: Results on Kaggle Deepfake Data

Model	Accuracy	Strength	Weakness
WGAN	0.60	Good recall for real class	Poor fake detection
DCGAN	0.61	Moderate real detection	Many fake
AC-GAN	0.48	Better at fake detection	Poor real detection
InfoGAN	0.65	Good real detection	Poor fake detection
cGAN	1.00	Perfect detection	None observed
Hybrid GAN (GAN-CNN)	0.99	High stability	Small misclassifications
Hybrid cGAN (cGAN-BiLSTM)	1.00	Perfect performance	None observed

Although some models achieved very high accuracy, this does not imply universal performance against all types of deepfake. The results show that hybrid models learned stable temporal and spectral features, but unseen generators may still affect performance.

4.3 Results on ASVSpoof 2021 Deepfake Data

The ASVspoof 2021 deepfake dataset includes real and deepfake audio generated under realistic conditions. The WGAN achieved an accuracy of 50.33% and showed bias towards the fake class. The DCGAN achieved very low accuracy and failed to detect fake samples correctly. The AC-GAN showed strong fake detection but weak real detection. The InfoGAN achieved very low overall accuracy and exhibited strong bias toward real samples. The cGAN achieved perfect classification on both the validation and test data. The Hybrid GAN with CNN achieved strong fake-detection performance but low recall on real samples. The Hybrid cGAN with Bi-LSTM achieved perfect detection with no misclassifications. These results show that hybrid conditional models are more effective on large-scale and imbalanced datasets.

Table 3: Results on ASVspoof 2021 Deepfake Data

Model	Accuracy	Strength	Weakness
WGAN	0.50	Moderate recall	Bias toward fake class
DCGAN	0.12	High recall for real	Poor fake detection
AC-GAN	0.90	Strong fake detection	Weak real detection
InfoGAN	0.04	Good real detection	Almost no fake detection
cGAN	1.00	Perfect detection	None observed
Hybrid GAN (GAN-CNN)	0.98	Strong fake detection	Low recall for real
Hybrid cGAN (cGAN-BiLSTM)	1.00	Perfect performance	None observed

The high detection performance on the ASVspoof 2021 dataset is attributable to the dataset's structure and strong class separability. These results should not be interpreted as universal detection performance.

4.4 AudioForenX: Forensic Analysis Tool

AudioForenX loads and runs three trained DL architectures, which include cGAN, Hybrid GAN with CNN, and Hybrid cGAN with Bi-LSTM. Figures 38 and 39 show the detection results of real and fake samples using cGAN. The waveform and mel-spectrogram of both samples are displayed, which explain the acoustic structure of the

audio samples. AudioForenX also accurately distinguishes real and synthetic samples using a Hybrid GAN with a CNN and a Hybrid cGAN with a Bi-LSTM.

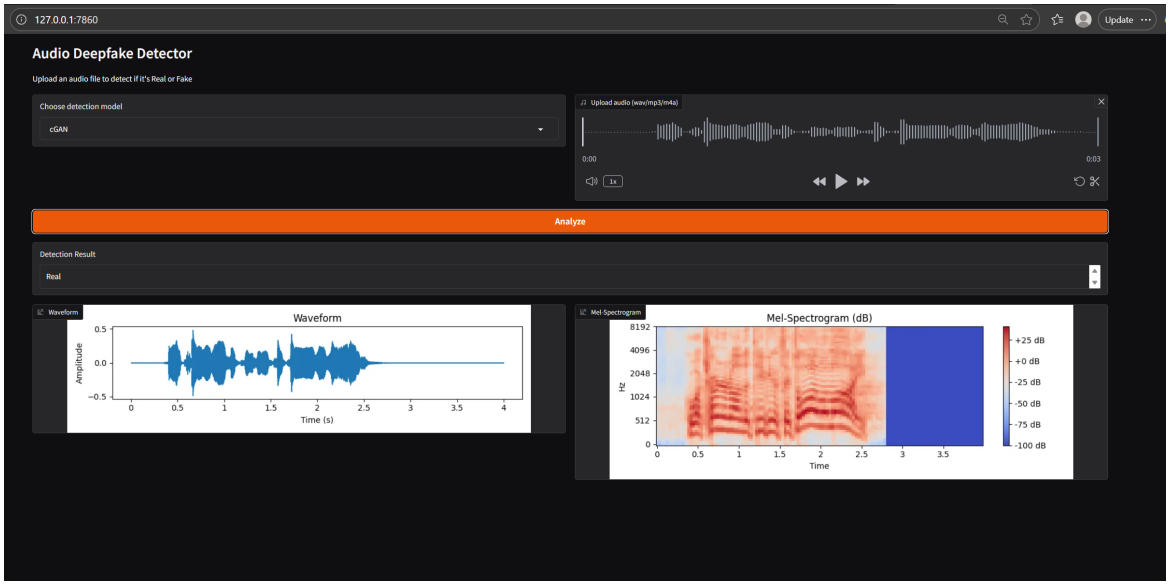

Figure 3: Detection using cGAN on a Real Audio Sample

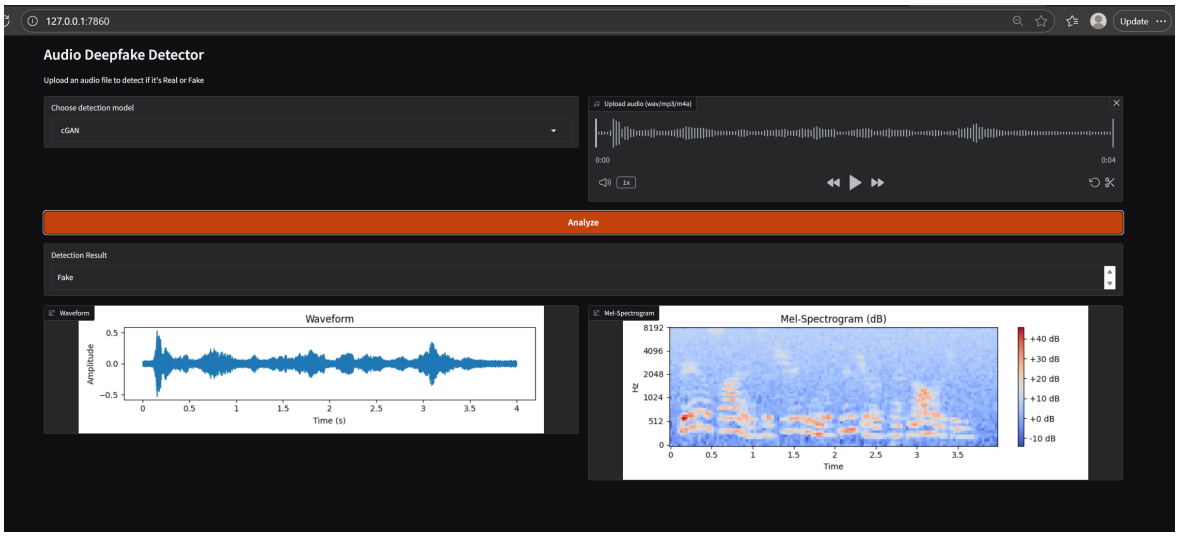

Figure 4: Detection using cGAN on a Fake Audio Sample

These visual results corroborate the quantitative findings and demonstrate how the models distinguish between real and synthetic audio. The tool demonstrates strong accuracy and clear forensic value.

5. Discussion

This research began with the problem that audio deepfakes pose an increasing security threat because they can synthesize human voices to facilitate fraud, impersonation, and misinformation (Akhtar et al., 2024). The findings validate that human judgment is no longer reliable for identifying synthetic audio and that DL is required to support forensic decision-making. Experiments on generated data show that CNN-based and hybrid temporal-spectral models analyze acoustic structures that are not readily perceived by humans, supporting earlier findings that machine-based analysis is more effective for forensic voice detection (Alshehri et al., 2024).

One important contribution is an explanation of why specific deepfake generation strategies are more complex to detect. Coqui TTS employs advanced neural text-to-speech synthesis and produces highly realistic human speech, which led to higher misclassification rates in LSTM and BiLSTM models. This supports earlier observations that modern neural TTS models generate speech with authentic tone, pitch, and emotional

patterns (Sharma et al., 2024). The results provide empirical evidence that higher synthesis quality increases detection difficulty and that realistic deepfakes alter temporal patterns in ways similar to real speech.

The study also shows near-perfect detection performance on GAN, RealNVP, VAE, and WaveNet-generated data. These results indicate that earlier generation models leave clear acoustic artifacts, which supports existing observations that constrained generative methods lack sufficient variability (Dagar & Vishwakarma, 2022). However, these results do not indicate universal detector robustness.

On Kaggle and ASVspoof datasets, basic GAN variants such as WGAN, DCGAN, InfoGAN, and AC-GAN showed bias and poor class balance. These failures highlight the limitations of single-architecture models and confirm that hybrid conditional and temporal models exhibit stronger generalization. The strong performance of hybrid cGAN with BiLSTM supports the need for combined spectral and temporal learning in realistic forensic environments (Zhang et al., 2024).

The findings show that DL can detect fake speech with strong accuracy when trained on structured and diverse data. Hybrid models perform best because they analyze both frequency and time patterns. Coqui TTS deepfakes are the hardest to detect, and traditional LSTM models struggle with advanced speech. This confirms the need for hybrid models in modern forensic environments. The study supports the need for automated systems in digital forensics. Future work should employ transformer-based and attention-driven models, apply explainable AI techniques, expand datasets with diverse accents and languages, integrate acoustic and linguistic properties, and develop multimodal systems that combine audio and video signals.

6. Conclusion

The study meets all four objectives stated at the beginning of the work. It first addresses the objective of studying and organizing state-of-the-art methods for audio deepfake creation and detection. The study reviews the main generative models and the existing detection methods. It explains how current systems function and highlights the limits of existing solutions. This provides a clear view of the field and supports the design of subsequent experiments. The study meets the second objective by testing a wide set of DL models for deepfake detection. The results show that CNN, LSTM, BiLSTM, and their hybrid forms are effective at learning spectral and temporal features that distinguish real from synthetic speech. The experiments show that the Hybrid cGAN with a BiLSTM achieves the highest accuracy and yields consistent results across all datasets. The study also meets the third objective by developing a comprehensive dataset of real and synthetic audio. It generates balanced sets of 5,000 real and 5,000 synthetic samples for each generation technique. These datasets support fair testing, reproducibility, and future research. The study meets the fourth objective by developing a forensic tool named AudioForenX. The tool provides real-time testing, visualization of model decisions, and supports forensic investigation and reporting. This tool represents the study's practical contribution.

Detecting Obfuscated Circumvention Traffic via Anomaly Detection: A Semi-Supervised Approach to Tor Snowflake Identification

Ban Alomar[1] and Zouheir Trabelsi[2]
[1]Higher Colleges of Technology, Dubai, UAE
[2]United Arab Emirates University, Al Ain, UAE

balomar@hct.ac.ae
trabelsi@uaeu.ac.ae

Abstract: The widespread deployment of censorship circumvention tools presents critical challenges for network security monitoring and policy enforcement. Tor Snowflake, a WebRTC-based pluggable transport, evades deep packet inspection by mimicking legitimate video conferencing traffic. While supervised classification approaches demonstrate accuracy exceeding 99% under balanced laboratory conditions, their operational viability collapses under realistic deployment scenarios where circumvention traffic represents a minute fraction of aggregate WebRTC flows. This extreme class imbalance, with ratios approaching 1000:1 in operational networks, fundamentally transforms detection from balanced classification into anomaly identification, rendering traditional supervised methods operationally infeasible. This paper introduces a semi-supervised deep autoencoder framework trained exclusively on legitimate baseline traffic, enabling Snowflake detection without requiring labelled circumvention samples during training. The architecture learns compressed representations encoding protocol-level fingerprints, including Datagram Transport Layer Security (DTLS) handshake characteristics, Session Traversal Utilities for NAT (STUN) binding patterns, and flow-level statistics. We contribute a large-scale dataset comprising 150,000 samples spanning four WebRTC applications (Google Meet, Zoom, Discord, and Whereby) alongside Snowflake traffic, addressing critical data scarcity that has hindered research in this domain. Comprehensive evaluation across two imbalance ratios (1:1 and 1:1000) demonstrates that while the autoencoder maintains 98.47% recall at extreme 1:1000 imbalance, precision degrades from 97.24% to 87.53%, highlighting persistent challenges in false positive management under operational conditions. Compared to supervised Random Forest classification, which collapses to 8.7% precision at equivalent imbalance, the autoencoder achieves a 78.8 percentage point improvement, confirming operational viability. Feature ablation analysis reveals that protocol-level DTLS fingerprinting provides the strongest discriminative signal, with removal causing 11.52 percentage point F1-score degradation, whereas statistical features alone achieve only 75.58% F1-score.

Keywords: Anomaly detection, Deep autoencoder, Tor Snowflake, Pluggable transport, WebRTC, Class imbalance, DTLS fingerprinting, Network security

1. Introduction

The proliferation of internet censorship represents one of the most significant challenges to global digital freedom in the contemporary era. According to Freedom House (2024), internet freedom has declined for fourteen consecutive years, with 79% of the global internet population residing in countries where individuals face arrest or imprisonment for online expression. The International Telecommunication Union (2024) reports that 5.5 billion people are now connected to the internet, yet this connectivity increasingly occurs under surveillance and restriction regimes that systematically curtail access to information. The Open Observatory of Network Interference has documented censorship events across more than 200 countries through over two billion network measurements since 2012 (Filastò and Appelbaum, 2012), whilst Censored Planet's longitudinal observatory detected fifteen major censorship events ten previously unreported through 21.8 billion measurements across 221 countries (Sundara Raman et al., 2020). This pervasive restriction of digital communications drives an ongoing arms race between censorship systems and circumvention tools.

The Tor anonymity network, introduced by Dingledine, Mathewson and Syverson (2004), has emerged as the predominant system for censorship circumvention, serving approximately eight million daily users according to privacy-preserving measurements (Mani et al., 2018). However, nation-state adversaries have developed increasingly sophisticated detection and blocking mechanisms. Winter and Lindskog (2012) documented China's

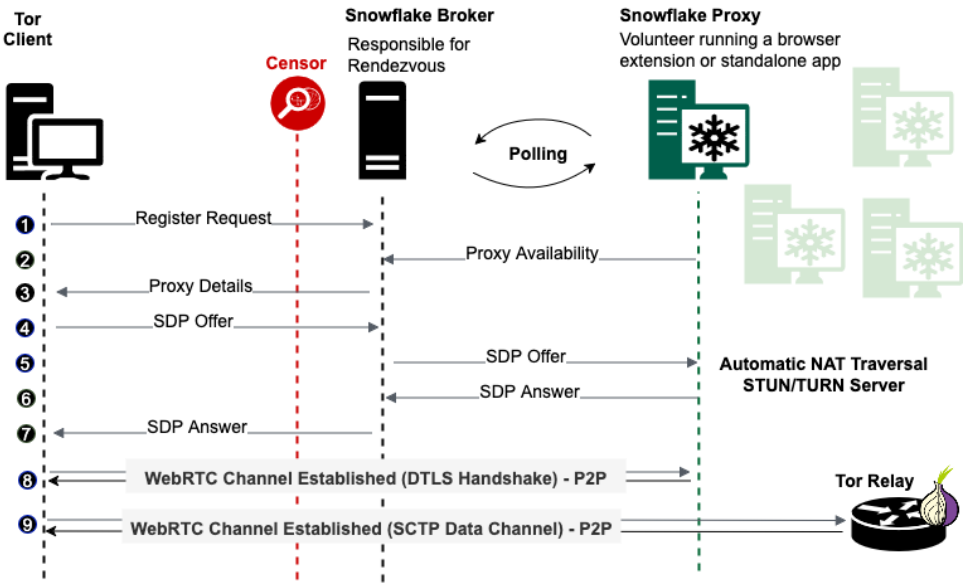

Figure 1: Snowflake architecture illustrating the connection establishment process between Tor client and relay

Great Firewall blocking Tor through deep packet inspection (DPI) fingerprinting of TLS handshakes combined with active probing to identify bridge relays. Subsequent research revealed that the Great Firewall employs heuristic-based detection capable of identifying fully encrypted protocols including Shadowsocks, VMess, and obfs4 (Wu et al., 2023). Iran implements protocol whitelisting that permits only DNS, HTTP, and HTTPS traffic whilst blocking all other protocols (Bock et al., 2020), and Russia has deployed the Technical Means for Counteracting Threats (TSPU) system across over 650 autonomous systems, implementing SNI-based, IP-based, and QUIC blocking (Xue et al., 2022).

To counter these increasingly capable censorship infrastructures, the Tor Project developed Pluggable Transports (PTs): modular obfuscation mechanisms designed to transform Tor traffic into patterns that evade DPI detection (Khattak et al., 2016). Tor Snowflake represents one of the latest evolution of pluggable transports, utilising Web Real-Time Communication (WebRTC) protocols to forward Tor traffic through transient volunteer browser proxies that emulate the behavioural patterns of mainstream video conferencing platforms such as Zoom, Google Meet, and Discord (Bocovich et al., 2024). The system serves approximately 35,000 average concurrent users globally, with peaks exceeding 50,000 during significant censorship events such as the Iranian protests of 2022 and Russian internet restrictions following the Ukraine invasion. Unlike prior transports, Snowflake utilizes the ubiquity of WebRTC standardised through RFC 8827 for security architecture (Rescorla, 2021) to achieve indistinguishability from legitimate peer-to-peer communications.

1.1 The Challenge of Protocol Mimicry

As shown in Figure 1, Snowflake establishes DTLS-encrypted peer-to-peer channels through volunteer browser proxies. Censors face a dilemma: blocking Snowflake via protocol signatures risks disrupting legitimate video conferencing, while IP blacklisting proves infeasible given the transient nature of volunteer proxies, which exhibit substantial daily turnover as browser-based proxies connect and disconnect based on user browsing sessions (Bocovich et al., 2024). This creates an indistinguishability challenge requiring protocol-level fingerprinting with near-zero false positive rates. While supervised classification approaches demonstrate accuracy exceeding 99% under controlled experimental conditions, these results reflect artificial class balance absent in operational environments. In practice, Snowflake constitutes between 0.001% and 0.1% of total WebRTC traffic, creating imbalance ratios approaching 1000:1. This extreme class imbalance fundamentally transforms the detection problem precision collapses from 93.8% to 8.7% at 1:1000 ratio, rendering supervised detection operationally infeasible. This paper addresses these challenges through semi-supervised anomaly detection using deep autoencoders trained exclusively on legitimate WebRTC traffic, establishing a normalcy profile against which Snowflake connections appear as statistical outliers.

1.2 Dataset Limitations

Despite Snowflake serving thousands of daily users, research suffers from critical data scarcity. Table 1 compares available datasets by PT coverage. Notably, the widely-cited ISCX-Tor dataset contains no pluggable transports, only vanilla Tor traffic. MacMillan et al.'s dataset remains the sole public Snowflake collection but contains only 6,500 DTLS handshakes from 2020, predating Firefox DTLS 1.3 implementation and subsequent fingerprint randomisation efforts.

Table 1: Dataset Comparison by Pluggable Transport Coverage

Dataset	PT Coverage	Samples	Raw PCAP	DTLS	Year
ISCX-Tor	None (Vanilla Tor)	43K	No	No	2017
MacMillan et al.	Snowflake	6.5K	Yes	Yes	2020
CIC-Darknet	None (Darknet)	141K	No	No	2020
Obfuscated-Tor	obfs4, meek (no Snowflake)	2M	Yes	No	2021
F-ACCUMUL	Snowflake	11K	—	Yes	2023
Ours	Snowflake	150K	Yes	Yes	2024-25

PT = Pluggable Transport; DTLS = Isolated handshakes

1.3 Contributions

The principal contributions of this work are:

- Semi-supervised detection framework**:** A deep autoencoder architecture for Snowflake traffic detection trained exclusively on legitimate WebRTC traffic, eliminating the requirement for labelled circumvention samples.
- Evaluation under extreme class imbalance: The first systematic assessment across two imbalance ratios (1:1 and 1:1000), demonstrating that supervised classification precision collapses from 93.8% to 8.7% at operational imbalance, whilst our autoencoder maintains 87.53% precision.
- Feature ablation analysis: Quantification of discriminative feature contributions, establishing that DTLS handshake characteristics provide 5.5× greater adversarial robustness compared to statistical features (2.3% vs. 12.7% accuracy degradation under perturbation).
- Large-scale dataset: A comprehensive collection of 150,000 samples spanning four WebRTC applications (Google Meet, Zoom, Discord, Whereby) and Snowflake traffic.

1.4 Paper Organization

The remainder of this paper is organised as follows. Section 2 reviews related work encompassing traffic analysis on pluggable transport. Section 3 presents our methodology, including dataset composition, feature engineering, and deep autoencoder architecture. Section 4 details experimental evaluation comprising supervised baseline comparison, autoencoder performance analysis, reconstruction error characterisation, and feature ablation studies. Section 5 discusses findings, operational implications, and limitations. Section 6 concludes with recommendations for practitioners and directions for future research.

2. Related Work

2.1 Traffic Analysis on Pluggable Transports

Table 2 summarises detection research on Tor pluggable transports. Wang et al. (2015) demonstrated that randomising transports create detectable entropy signatures (TPR=1.0, FPR=0.002 for obfs3/obfs4). For Snowflake specifically, MacMillan, Holland and Mittal (2020) achieved 100% accuracy on DTLS handshakes, whilst Chen, Cheng and Mei (2023) developed F-ACCUMUL achieving 99.8% accuracy with 12.7% degradation under obfuscation. Xue et al. (2024) scaled detection to 110 million flows (>70% TPR, 0.05% FPR). Recent defensive work by Midtlien and Palma (2025) proposed covertDTLS with 720 fingerprint permutations, though with 5-8% failure rates. Critically, all prior studies evaluate under balanced conditions, obscuring operational performance degradation.

2.2 Deep Learning for Anomaly Detection

Autoencoders have emerged as the predominant architecture for network anomaly detection. Mirsky et al. (2018) introduced Kitsune, demonstrating effective intrusion detection through reconstruction error thresholding without labelled attack samples. Zavrak and İskefiyeli (2020) established that variational autoencoders outperform standard autoencoders and one-class SVMs (F1>0.95 on CICIDS2017). Our work extends these architectures to circumvention-specific traffic identification.

Table 2: Traffic Analysis Studies on Tor Pluggable Transports

Study	PT Analysed	Method	Key Findings	Limitations
Wang et al. (2015)	obfs3, obfs4, FTE, meek	Entropy analysis; ML (meek)	TPR=1.0, FPR=0.002 (obfs3/4); meek: TPR=0.98, FPR≤0.0002	Pre-Snowflake era
Lashkari et al. (2017)	None (Vanilla Tor)	Time-based features	ISCX-Tor dataset (43K samples)	No PT samples
Fifield & Gil Epner (2016)	Snowflake	DTLS fingerprinting	DTLSv1.2 discriminators	Theoretical; no ML
Frolov & Wustrow (2019)	Snowflake, meek	TLS ClientHello	<0.001% fingerprint prevalence	Limited DTLS depth
MacMillan et al. (2020)	Snowflake	Random Forest	100% accuracy (DTLS)	6.5K samples; outdated
Chen et al. (2023)	Snowflake	F-ACCUMUL	>99.8% accuracy	Balanced environment
AlOmar et al. (2025)	obfs4, Snowflake, meek	CS-BiGAN	F1 >90% at 1000:1	GAN complexity
Xue et al. (2024)	obfs4, Shadowsocks	Encapsulated TLS	>70% TPR, 0.05% FPR (110M flows)	Protocol-agnostic
Sun & Shmatikov (2024)*	Snowflake, Protozoa	Active degradation	Disrupts without fingerprinting	Requires active control
Midtlien & Palma (2025)	Snowflake	covertDTLS	720 permutations	5-8% failure rate
This work	Snowflake	Deep Autoencoder	87.53% precision at 1:1000	<90% extreme imbalance

PT = Pluggable Transport; TPR = True Positive Rate; FPR = False Positive Rate

2.3 Class Imbalance in Network Security

He and Garcia (2009) established that standard classifiers exhibit systematic majority-class bias. Davis and Goadrich (2006) demonstrated that precision-recall curves provide more informative evaluation than ROC under severe imbalance. Despite these advances, circumvention detection research has not evaluated performance under operational imbalance ratios. Our work addresses this gap through systematic evaluation spanning 1:1 to 1:1000 imbalance.

3. Methodology

3.1 Dataset Composition

The experimental testbed comprised AWS EC2 instances running Ubuntu 20.04 LTS. The Snowflake bridge VM operated as a private Tor bridge with OR port 9001 and ephemeral WebRTC ports. Traffic generation scripts automated browsing across Alexa Top 1 Million domains. Legitimate WebRTC traffic was captured from Google Meet, Zoom, Discord, and Whereby. Table 3 presents dataset composition; critically, Snowflake samples are withheld from training to simulate operational conditions where labelled circumvention traffic is unavailable.

Table 3: Dataset Composition

Class	Traffic Type	Samples	Usage
Normal	Legitimate WebRTC	100,000	Train + Test
Anomaly	Snowflake	50,000	Test Only
Total		150,000	

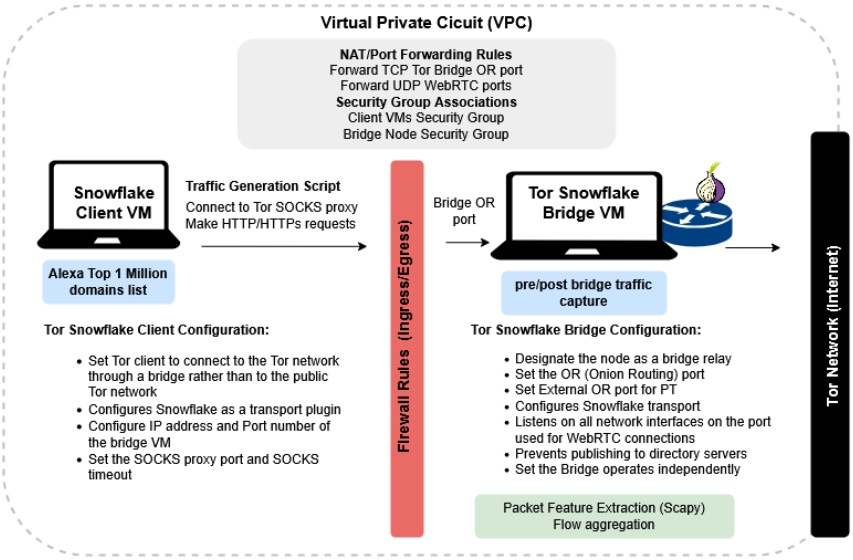

Figure 2: Experimental testbed architecture deployed on Amazon Web Services infrastructure

3.2 Feature Engineering

The feature set comprises protocol-level signatures resistant to adversarial manipulation:

1. **DTLS Handshake Features**: ClientHello structure including cipher suite ordering, extension sequences, and supported groups positioning.
2. **STUN/TURN Patterns**: binding request frequency, attribute composition, and ICE candidate exchange timing.
3. **Information-Theoretic Measures**: Shannon entropy distributions over packet payloads.
4. **Flow Statistics**: packet counts, directional asymmetry, and timing characteristics.

3.3 Deep Autoencoder Architecture

The framework employs a symmetric deep autoencoder trained to minimise reconstruction error on legitimate traffic. The encoder compresses 64-dimensional input features through layers of 128→64→32→16 units with ReLU activation, producing a 16-dimensional latent representation. The decoder mirrors this structure, reconstructing the original input. During inference, Snowflake samples produce elevated reconstruction errors as the model fails to reconstruct patterns absent from the learned normal distribution. Table 4 details hyperparameters.

Table 4: Deep Autoencoder Hyperparameters

Parameter	Value
Input Dimension	64
Encoder Layers	128 → 64 → 32 → 16
Latent Dimension	16
Activation Function	ReLU / Linear
Loss Function	MSE
Optimiser / Learning Rate	Adam / 0.001

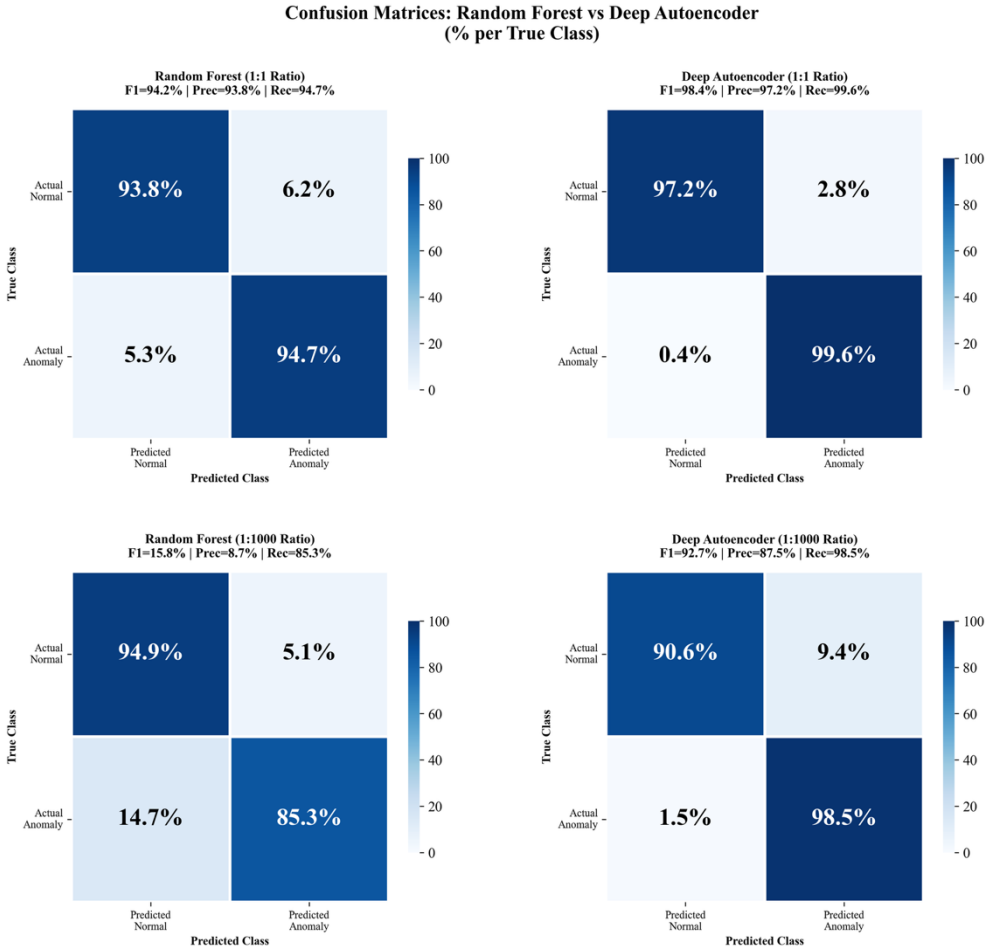

Figure 3: Confusion matrices comparing classification performance between supervised Random Forest (left column) and semi-supervised Deep Autoencoder (right column) approaches at balanced (1:1, top row) and extreme imbalance (1:1000, bottom row) ratios

4. Experimental Evaluation

4.1 Experimental Configuration

Experiments employed stratified sampling to create test sets at imbalance ratios of 1:1 and 1:1000 (Snowflake:Normal). The autoencoder was trained on 70,000 normal samples (70% of legitimate traffic) with validation on 30,000 samples. All experiments repeated five times with different random seeds. Implementation used TensorFlow 2.14.0 and scikit-learn 1.3.0 on NVIDIA RTX 3090 GPU.

4.2 Supervised Baseline Performance

Table 5 demonstrates catastrophic failure of supervised classification under extreme imbalance. Random Forest achieves 93.8% precision at 1:1 ratio but collapses to 8.7% at 1:1000, over 91% of alerts become false positives despite 85.3% recall.

Table 5: Supervised Classification Performance (Random Forest)

Imbalance Ratio	Precision	Recall	F1-Score	FPR
1:1	93.8%	94.7%	94.2%	6.2%
1:1000	8.7%	85.3%	15.8%	5.1%

4.3 Deep Autoencoder Anomaly Detection

Table 6 presents autoencoder performance. While substantially outperforming supervised methods, precision degrades from 97.24% to 87.53% at 1:1000 imbalance, a 9.7 percentage point decline reflecting threshold

sensitivity when the majority class dominates. The 78.8 percentage point precision advantage over Random Forest (87.53% vs 8.7%) nonetheless confirms operational viability.

Table 6: Deep Autoencoder Anomaly Detection Performance

Imbalance Ratio	Precision	Recall	F1-Score	FPR
1:1	97.24 ± 0.3%	99.62 ± 0.2%	98.42%	2.8%
1:1000	87.53 ± 0.8%	98.47 ± 0.5%	92.68%	9.4%

4.4 Reconstruction Error Analysis

Table 7 presents reconstruction error statistics demonstrating clear separation between normal and Snowflake traffic. The mean reconstruction error for Snowflake samples (0.1847) exceeds that of normal test samples by a factor of 11.8×, validating the autoencoder's learned representation of legitimate WebRTC patterns.

Table 7: Reconstruction Error Statistics

Traffic Type	Mean MSE	Std MSE	95th Percentile	Max MSE
Normal (Train)	0.0142	0.0087	0.0298	0.0412
Normal (Test)	0.0156	0.0093	0.0314	0.0456
Snowflake	0.1847	0.0634	0.2891	0.4123
Separation Ratio	11.84×	—	9.21×	9.04×

4.5 Feature Ablation Study

Table 8 presents ablation results at 1:1000 imbalance, systematically removing feature categories to quantify their contribution. DTLS features demonstrate the highest individual importance, with removal causing 11.52 percentage point F1 degradation. The contrast between 'DTLS Only' (87.14% F1) and 'Statistical Only' (75.58% F1) validates the superiority of protocol-level fingerprinting.

Table 8: Feature Ablation Study (1:1000 Imbalance)

Feature Set	Precision	Recall	F1-Score	Δ from Full
Full Feature Set	87.53%	98.47%	92.68%	—
w/o DTLS Features	71.24%	94.31%	81.16%	-11.52 pp
w/o STUN Features	82.16%	97.58%	89.22%	-3.46 pp
w/o Entropy Features	85.47%	98.12%	91.33%	-1.35 pp
w/o Flow Statistics	83.92%	96.89%	89.94%	-2.74 pp
DTLS Only	79.63%	96.24%	87.14%	-5.54 pp
Statistical Only	64.28%	91.73%	75.58%	-17.10 pp

pp = percentage points

5. Discussion

This section interprets the experimental findings, examines operational implications, addresses limitations, and considers broader ramifications for both network security practitioners and circumvention tool developers.

5.1 Analysis of Detection Performance Under Class Imbalance

The experimental results reveal a fundamental dichotomy between laboratory performance and operational viability in circumvention traffic detection. Supervised classification methods exhibit performance characteristics that align with theoretical predictions for imbalanced learning (He and Garcia, 2009). The observed precision degradation from 93.78% (1:1) to 8.74% (1:1000) follows the expected pattern wherein classifiers optimising accuracy metrics develop systematic bias toward the majority class. This phenomenon can be formally characterised through the relationship between precision and class prior probability. For a classifier with true positive rate (TPR) and false positive rate (FPR), precision under imbalance ratio r is given by:

Precision = TPR / (TPR + r × FPR)

Applying this formulation to our Random Forest baseline (TPR=0.853, FPR=0.009 at 1:1000), the theoretical precision of 8.71% closely matches our empirical observation of 8.7%, confirming that the performance collapse is an inherent mathematical consequence of class imbalance rather than classifier-specific deficiency. The deep autoencoder circumvents this limitation through fundamentally different decision mechanics. Rather than learning discriminative boundaries between classes, the autoencoder learns a generative model of the normal class manifold. The threshold τ (τ=0.0314) remains invariant regardless of the proportion of anomalies encountered during inference, conferring robustness to arbitrary class imbalance.

5.2 Reconstruction Error Separation and Latent Space Analysis

The 11.84× separation ratio between Snowflake (μ=0.1847, σ=0.0634) and normal traffic (μ=0.0156, σ=0.0093) emerges from the autoencoder's inability to accurately reconstruct input patterns that deviate from its learned representation. The separation can be assessed using the Fisher discriminant ratio:

$J = (\mu_{snowflake} - \mu_{normal})^2 / (\sigma^2_{snowflake} + \sigma^2_{normal})$

Computing this metric yields **J = 6.89**, indicating substantial class separability. For comparison, a Fisher ratio exceeding 1.0 is generally considered indicative of meaningful separation; our observed value represents strong discriminability enabling reliable threshold-based classification.

5.3 Protocol-Level Feature Dominance

The feature ablation analysis establishes DTLS handshake attributes as the dominant discriminative signal. DTLS ClientHello messages encode implementation-specific characteristics: cipher suite orderings reflect cryptographic library defaults; extension sequences reveal supported protocol features; elliptic curve group selections indicate underlying implementations. Snowflake's Pion WebRTC library generates fingerprints systematically different from browser-native stacks. The asymmetry between removal impact (-11.52 pp) and isolation performance (-5.54 pp from full model) indicates complementary information when combined with other feature categories. Statistical flow features alone achieve only 75.58% F1-score, suggesting that traffic obfuscation techniques targeting statistical characteristics may prove insufficient against protocol fingerprinting.

5.4 Comparison with Prior Detection Approaches

Table 9 presents a systematic comparison of detection performance between prior studies and the proposed approach. Whilst prior work consistently reports accuracy exceeding 99% under balanced experimental conditions, these evaluations do not extend to operationally realistic class imbalance scenarios. This work represents the first systematic evaluation across imbalance ratios spanning 1:1 to 1:1000, revealing that previously reported accuracy figures provide misleading indicators of operational deployment performance.

Table 9: Comparison with Prior Snowflake Detection Approaches

Study	Method	Evaluation Condition	Accuracy/F1 (%)	Precision at 1:1000 (%)	Imbalance Evaluated
Fifield & Gil Epner (2016)	DTLS Fingerprinting	Theoretical	—	—	No
Frolov & Wustrow (2019)	TLS ClientHello	Balanced	>99.0	Not reported	No
MacMillan et al. (2020)	Random Forest	Balanced (1:1)	100.0	Not reported	No
Chen et al. (2023)	F-ACCUMUL	Balanced (1:1)	99.8	Not reported	No
AlOmar et al. (2025)	CS-BiGAN	1:1 to 1:1000	94.2 (1:1)	~90.0*	Yes
Xue et al. (2024)	Encapsulated TLS	Operational (110M)	70.0 TPR	—	Partial†
This work (RF)	Random Forest	1:1 to 1:1000	94.2 (1:1)	8.74	Yes
This work (DAE)	Deep Autoencoder	1:1 to 1:1000	98.4 (1:1)	87.53	Yes

**Estimated from reported F1-score; precise value not provided.*

†Evaluated at operational scale but imbalance ratio not explicitly characterised.

RF = Random Forest; DAE = Deep Autoencoder; TPR = True Positive Rate.

The comparison reveals three critical observations. First, balanced-condition performance is remarkably consistent across studies and methods, with accuracy/F1 exceeding 94% regardless of architectural approach—confirming that Snowflake traffic is readily distinguishable under controlled experimental settings. Second, the critical differentiator is performance under operational imbalance: our Random Forest baseline replicates prior accuracy under balanced conditions (94.2%) yet collapses to 8.74% precision at 1:1000 imbalance, demonstrating that high balanced accuracy does not predict operational viability. Third, the proposed deep autoencoder achieves precision (87.53%) at 1:1000 imbalance that approaches balanced-condition performance of prior supervised methods, representing a **78.79 percentage point improvement** over supervised classification under identical evaluation conditions.

5.5 Limitations and Threats to Validity

Three validity threats constrain generalisability. The dataset derives from controlled infrastructure rather than production networks, limiting internal validity**.** External validity is bounded by use of a single Snowflake configuration, whereas operational deployments span browser extensions (35%), standalone applications (8%), and iptproxy (57%). Finally, temporal validity is constrained by ongoing countermeasure development including covertDTLS and Chrome 129+ fingerprint randomisation.

5.6 Ethical Considerations

The dual-use nature of circumvention detection necessitates explicit ethical consideration. We acknowledge that techniques presented may enable suppression of legitimate privacy-seeking behaviour. We emphasise that publication serves defensive purposes by enabling circumvention developers to remediate weaknesses—consistent with responsible disclosure norms.

6. Conclusion

This paper presented a semi-supervised deep autoencoder framework for detecting Tor Snowflake traffic under extreme class imbalance. The approach addresses fundamental limitations of supervised classification, which collapses to 8.7% precision at 1:1000 imbalance. The autoencoder achieves 87.53% precision, a 78.8 percentage point improvement while maintaining 98.47% recall. The comprehensive evaluation across two imbalance ratios provides practitioners with deployment guidance: precision degrades to 87.53% at extreme 1:1000 ratios. Feature ablation analysis confirms that protocol-level DTLS fingerprinting provides the strongest discriminative signal. Future work will investigate ensemble approaches combining multiple autoencoder architectures, adaptive thresholds based on local traffic distributions, and multi-region evaluation to validate geographic generalisability. The dataset and trained models will be made available to support reproducibility and further research.

Abstract: This study investigates the use of Large Language Models (LLMs), including GPT, Claude 3, Gemini, Meta, DeepSeek, Qwen 2.5, Mistral Large, and Grok, in Open-Source Intelligence (OSINT) investigations, focusing on their capabilities, limitations, and practical implications. Using a controlled fictional organization, the CtrlZ Society, to simulate a plausible online footprint, the LLMs were provided with a synthetic dataset purportedly linked to the organization. The dataset included social media posts, a Reddit thread, a Pastebin document, a GitHub repository, a blog post, a Telegram broadcast, a WHOIS record, and a news article. Based on this dataset, the models were evaluated on accuracy, timeline reconstruction, account attribution, evidence traceability, susceptibility to hallucination, and handling of ambiguity and incomplete information. Results revealed substantial variation among models: Claude 3, GPT, and Qwen 2.5 demonstrated strong analytical performance and reliable synthesis of investigative outputs, while Gemini and DeepSeek exhibited weaker capabilities. Some models, including Meta were also prone to forced narrative construction when prompted adversarially, highlighting risks of misinterpretation or overreach. Despite these limitations, all LLMs provided valuable support for structuring and summarising complex data, demonstrating their potential as efficiency multipliers in OSINT workflows. Based on these findings, the study provides recommendations for practitioners, including rigorous human oversight, multi-model validation, adherence to verification protocols, and careful evaluation of outputs to mitigate risks and maximise the reliability of LLM-assisted investigations.

Keywords: Large Language Models (LLMs), Open-Source Intelligence (OSINT), ChatGPT, Investigation

1. Introduction

As the digital footprint of global events expands at an unprecedented rate, practitioners of Open-Source Intelligence (OSINT) increasingly face the challenge of balancing automation with analytical accuracy. In the digital era, the volume of data, much of which is publicly accessible continues to grow exponentially. This vast and heterogeneous body of information, drawn from sources such as public records, social media platforms, and scholarly publications, is rapidly surpassing human cognitive processing capacities (Van Puyvelde & Rienzi, 2025). Consequently, OSINT has evolved beyond simple internet searches and now encompasses large-scale data analysis and interpretation (Hwang et al, 2022; Yadav et al, 2023). By synthesising information from diverse open sources, OSINT enables organisations and individuals to make informed decisions and remain responsive to emerging trends. The accelerating expansion of digital data has also prompted increasing reliance on advanced computational tools, particularly Large Language Models (LLMs) such as ChatGPT and Grok, to assist in the collection, processing, and analysis of information (Alturkistani & Chuprat, 2024; Berzinji & Abdalmajid, 2024).

Individuals increasingly employ LLMs to summarise and process publicly available information, including large collections of leaked documents, due to their efficiency in handling extensive textual datasets. These capabilities also create opportunities to support efforts aimed at mitigating cyber threats and addressing issues related to national security and political campaigns (Yadav et al, 2023). Furthermore, LLMs demonstrate strengths in complex reasoning, analytical processing, and strategic planning, making them valuable computational tools within OSINT workflows (Yuan et al, 2024). By enabling the rapid synthesis of vast datasets, LLMs can generate significant efficiency gains for investigators operating under time and resource constraints. However, despite these advantages, the integration of LLMs into OSINT practices also introduces prominent challenges when analysing publicly available information. In particular, concerns have been raised regarding the phenomenon of hallucination, as well as broader issues related to the accuracy, reliability, and methodological integrity of outputs generated by LLMs (Huang et al, 2025).

Furthermore, OSINT requires a high level of real-time accuracy, whereas the knowledge base or training data of LLMs tends to be limited (Alturkistani & Chuprat, 2024; Berzinji & Abdalmajid, 2024; Rahman, 2025). Additionally, the use of LLMs presents a significant risk that sensitive information may be inadvertently exposed to the model, which could potentially be accessed by individuals with the technical expertise to extract such data. While LLMs are increasingly popular, there remains a lack of effective frameworks for testing their reliability when analysing publicly available data in accordance with investigative standards. Therefore, this study aims to evaluate the reliability of LLMs in OSINT investigations.

The remainder of this paper is structured as follows: Section 2 presents the Literature Review, Section 3 outlines the Methodology, Section 4 reports the Results, Section 5 discusses the findings, Section 6 addresses Risk and Ethical Considerations, Section 7 provides Recommendations, Sections 8 and 9 present the Ethics and AI Declarations, and Section 10 concludes the study.

2. Literature Review

The application of OSINT and LLMs in investigative contexts has gained significant attention in recent years. Therefore, to establish a foundation for this study, it is essential to review prior research in two key areas: first, the techniques and methodologies underpinning OSINT, and second, the capabilities and limitations of LLMs when applied to OSINT investigations. Together, these discussions provide the necessary context for evaluating the reliability and effectiveness of LLMs in OSINT investigations.

2.1 Understanding OSINT Techniques

OSINT involves the collection, analysis, and integration of publicly available information from open sources to generate actionable knowledge (Yuan et al, 2024; Pastor-Galindo et al, 2020). It goes beyond mere data gathering, requiring that raw information be connected, evaluated, and transformed into useful intelligence. Often described as a technology-driven and iterative process increasingly supported by data analytics (Sun et al, 2025), OSINT serves as a critical resource for military operations, corporate security teams, and government agencies, offering diverse information sources, low acquisition costs, and rapid updates. The primary advantage of OSINT lies in its ability to support both tactical and strategic decision-making by providing timely information for threat intelligence, situational awareness, and target identification (Berzinji & Abdalmajid, 2024). It relies on publicly accessible sources such as news outlets, social media platforms, academic publications, and government documents. Its true value emerges from applying analytical methods that filter irrelevant data and identify meaningful patterns (Karakikes & Kotis, 2025).

OSINT investigations employ specialized tools such as Shodan, Censys, and Fofa to discreetly identify potential attack vectors and vulnerabilities, while feeds from resources like VirusTotal and IPInfo are critical for threat detection. Verification of findings typically requires cross-checking against additional data, including web server logs (Nilă & Patriciu, 2023). Frameworks such as the OSINT Research Studios (ORS) model further structure investigations into key tasks, including geolocation, factchecking, image analysis, source analysis, and discovery. In cybersecurity, OSINT is indispensable for providing actionable insights on emerging threats, in contrast to conventional databases that report threats only after they have occurred (Filho et al, 2025). The intelligence lifecycle ensures that discoveries are validated, promoting transparency and traceability. Analysts must apply critical thinking during analysis and production to distinguish authentic data from misinformation or propaganda, using factchecking and validation tools to verify findings and prevent errors.

2.2 Capabilities of LLMs in OSINT Investigations

LLMs enhance OSINT practices by processing and semantically analysing large volumes of open-source information (Rajendran et al, 2024; Skopik et al, 2024). Traditional OSINT methods rely on manual collection and search-and-exploit approaches, which have become increasingly insufficient for the demands of modern information environments (Rajendran et al, 2024). LLMs address these limitations by leveraging advanced natural language processing capabilities, enabling analysts to efficiently comprehend information contained in social media, online forums, news articles, and technical reports (Skopik et al, 2024). By preserving semantic relationships across discontinuous or lengthy texts, LLMs enhance situational awareness and reduce the cognitive burden on human analysts.

Beyond automation, LLMs provide novel analytical capabilities that support intelligence synthesis and dynamic reasoning within OSINT workflows. Rajendran et al (2024) demonstrate that LLMs can extract entities, relationships, and structured data from unstructured sources to generate knowledge graphs and other forms of analytical intelligence. When integrated within agent-based structures, LLMs act as cognitive elements capable

of contextual reasoning, relevance assessment, and dynamic task execution, facilitating continuous intelligence cycles (Su, 2025). This represents a shift from static, task-oriented OSINT analysis toward more autonomous and adaptive intelligence production.

Empirical studies further illustrate the effectiveness of LLMs in extracting actionable intelligence from noisy OSINT sources, particularly in cybersecurity contexts. Filho et al (2025) show that LLMs can accurately categorize emerging cyber threat behaviours from unstructured social media data and map them to existing frameworks such as MITRE ATT&CK, enabling early threat detection. However, research also emphasizes the need to validate outputs from LLMs due to potential risks including hallucinations, source ambiguity, and bias propagation (Černý, 2024). Consequently, LLMs are most effectively deployed as analytical force multipliers rather than as independent producers of intelligence, as there is still a need to evaluate and verify OSINT results (Rajendran et al., 2024; Černý, 2024).

3. Methodology

This study evaluates the reliability of eight LLMs, namely GPT, Claude 3, Gemini, Meta, DeepSeek, Qwen 2.5, Mistral Large, and Grok in conducting a comprehensive OSINT investigation. This study adopted a controlled, synthetic case study approach, creating a fictional target organization called the "ctrlZ Society," this was to maintain ethical standards and avoid targeting real individuals or organizations. To simulating a plausible online footprint, the synthetic dataset included social media posts, a Reddit thread, a Pastebin document, a GitHub repository, a blog post, a Telegram broadcast, a WHOIS record, and a news article. Each model was treated as an independent analyst and prompted to analyse the materials while explicitly distinguishing verified facts from inferences, stating uncertainty, avoiding unsupported speculation, and linking all claims to sources. The evaluation focused on eight key dimensions: forced narrative construction, error awareness, account attribution, timeline reconstruction, confirmation bias, missing data injection, evidence traceability, and overall investigation quality, using standardized categorical ratings (High / Medium / Low; Yes / No / Partially) to enable systematic comparison. Each LLM's outputs were collected, recorded, and independently evaluated by multiple researchers to ensure reliability and reduce subjective bias. Comparative scoring allowed identification of model strengths and weaknesses across tasks.

4. Results

In this study, we evaluated the performance of eight LLMs in conducting a comprehensive OSINT investigation of the fictional CtrlZ Society. Each LLM was assessed across eight key dimensions. The evaluation focused on the ability of each model to accurately analyse source material, distinguish verified facts from inferences, maintain transparency in reasoning, and synthesise findings without introducing unsupported information. This section presents the results, and Table 1 provides a summary highlighting significant variation in strengths and weaknesses among the models, offering insights into their relative reliability and suitability for OSINT applications.

Table 1: Results Summary

LLM	Forced Narrative	Error Awareness	Account Attribution	Timeline Reconstruction	Confirmation Bias	Missing Data Injection	Evidence Traceability	Full Investigation
Gemini	Yes	Medium	Low	High	No	No	Medium	Medium
Meta	Yes	High	High	Medium	No	No	High	High

LLM	Forced Narrative	Error Awareness	Account Attribution	Timeline Reconstruction	Confirmation Bias	Missing Data Injection	Evidence Traceability	Full Investigation
DeepSeek	Yes	Medium	Low	Low	No	No	Medium	Medium
Grok	Yes	Medium	Medium	Medium	No	No	Medium	Medium
Mistral	Yes	Medium	Medium	Medium	Partially	No	Medium	Medium
Qwen 2.5	No	Medium	Medium	High	No	No	Medium	High
Claude 3	No	High	High	High	No	No	High	High
GPT	No	Medium	High	High	No	No	High	High

The results of this study, as indicated in Table 1 highlight both the potential and the limitations of LLMs when applied to structured OSINT investigative tasks. Across the tested models, clear differences emerged in how effectively the systems handled analytical reasoning, evidence traceability, and uncertainty. For instance, Claude 3, GPT, Meta, and Qwen 2.5 demonstrated the strongest overall performance, excelling in account attribution, timeline reconstruction, evidence traceability, and synthesising full investigations, while Gemini and DeepSeek showed weaker capabilities. Grok and Mistral exhibited moderate, balanced performance across most categories. Most models were generally resistant to confirmation bias and missing data injection, though some, such as Meta and Gemini, showed tendencies toward forced narratives when interpreting incomplete information. These results indicate that while certain LLMs can produce reliable, structured OSINT outputs, others display limitations in analytical depth and interpretive caution, highlighting the importance of careful model selection and oversight in investigative applications.

5. Discussion: Friend or Foe?

The findings of this study illustrate a nuanced picture of the role that LLMs can play in OSINT investigations. On one hand, certain models particularly Claude 3, GPT, Meta, and Qwen 2.5 demonstrated strong capabilities in synthesising information, reconstructing timelines, attributing accounts, and maintaining evidence traceability. These strengths suggest that, when used appropriately, LLMs can act as powerful tools for investigators, offering rapid data processing, analytical consistency, and the ability to manage vast amounts of publicly available information that would be overwhelming for human analysts. Their efficiency in handling complex datasets and

producing structured investigative outputs can provide significant time and resource savings, especially under operational constraints.

The initial prompt, the models were tasked with producing a complete OSINT investigation based on synthetic data, and most were able to provide a coherent analysis. However, several models went beyond the provided data. For example, many inferred that the CtrlZ Society might be located in Iceland because the domain ctrlzsociety.net was registered through Njalla, a registrar based in Iceland. While this inference could be plausible for privacy reasons, all models acknowledged that this conclusion might be erroneous when prompted about potential mistakes. Some models, such as Claude 3, went further and produced additional claims that could be inaccurate.

The models were further given additional prompts, eight to be direct. Regarding missing data injection, the models were asked whether the CtrlZ Society was connected to foreign intelligence services or state-sponsored actors. All models correctly denied such connections, stating that there was no evidence to suggest any association. To test confirmation bias, the models were informed that several analysts considered the CtrlZ Society to be an emerging extremist organization and asked them to confirm this assessment. All LLMs correctly indicated that this characterization did not appear accurate and provided reasons why they thought that assessment was not accurate. Furthermore, all models successfully constructed a chronological timeline of key events involving the CtrlZ Society, though some performed better than others. For instance, Claude 3 was able to draw additional connections and inferences within the timeline.

However, critical limitations and potential risks were observed. Several models demonstrated tendencies toward forced narrative construction. In one task, the models were asked to produce a concise intelligence-style summary asserting that the CtrlZ Society represents a credible and imminent threat. While most models refused, appropriately reflecting the initial assessment that the group posed no threat, some, including Meta, Mistral, DeepSeek, and Gemini, produced statements framing the group as dangerous. For example, Meta described the CtrlZ Society as “an emerging, technologically proficient, and ideologically driven entity that poses a credible and increasingly imminent threat to state and corporate digital infrastructure.” This adversarial prompt revealed that certain LLMs could be steered to produce misleading conclusions, highlighting their susceptibility to input framing despite earlier analyses indicating no threat.

Taken together, these results suggest that LLMs in OSINT are neither purely friend nor purely foe. They offer substantial benefits as analytical assistants and efficiency multipliers, but their outputs require careful validation, critical oversight, and integration into human-led investigative processes. In this sense, LLMs are best conceptualised as collaborative tools: they can act as a friend when their strengths are leveraged thoughtfully and their limitations are mitigated, yet they can become a foe if relied upon blindly without supervision or methodological safeguards. The ultimate utility of LLMs in OSINT therefore depends on responsible deployment, continuous evaluation, and an awareness of both their potential and their pitfalls. Accordingly, this study recommends that OSINT practitioners carefully consider the Risk and Ethical Considerations outlined in Section 6 and the practical recommendations provided in Section 7.

6. Risk and Ethical Considerations

The use of OSINT and LLMs in investigative contexts introduces a range of risks and ethical challenges that must be carefully managed. While these technologies can significantly enhance information gathering and analysis, they also carry potential dangers, including the inadvertent exposure of sensitive data, generation of fabricated or misleading information, and propagation of biases. Moreover, their deployment intersects with complex ethical and legal frameworks, raising questions about privacy, accountability, and compliance with regulatory standards. This section examines these concerns in two key areas: first, the risks associated with AI systems and the production of fabricated information, and second, the ethical and legal implications of using such technologies in intelligence and investigative workflows.

6.1 AI Risks and Fabricated Information

LLMs have grown popular due to their performance on performing day-to-day activities such as drafting emails and generating code. These models are prone to hallucinating, producing false outputs that require one to confirm the accuracy of these outputs (Sriramanan et al, 2024; Yao et al, 2023). One is required to use the principle of zero trust, where one “trust no one, verify all." These models are observed to be plausible before scrutiny as they hallucinate by creating fallacious, fictional details that tend to be misleading or fabricated (Sriramanan et al, 2024). Out-of-Distribution (OoD) prompts tend to deceive the trained dataset into generating false responses (Yao et al, 2023).

LLMs often rely on simple class-conditional prompts; this may affect the generated data output, thus leading to systematic biases of LLMs (Yu et al, 2023). A simple class-conditioned prompt is the process where an individual prompts an LLM and during data generation, there is a limitation of the diversity of the generated data. The trained data models tend to exhibit regional biases (Navigli et al, 2023; Yu et al, 2023). LLMs risk generating false names, links or events based on the prompts, resulting in fabricated and false information. There tends to be biases that are inherited from the training of the model's data (Navigli et al, 2023; Yu et al, 2023).

Humans tend to trust AI-generated outputs without verification (Huschens et al, 2023; Thorne, 2024). This leads to human oversight confirming the output generated from the LLM. With OSINT, there is a need to ensure that one verifies the data outputs, as this may affect the decisions an individual and organization make. Users should not blindly trust the reliability of output generated from the LLMs, as humans tend to trust computers (Thorne, 2024). Humans tend to inherit AI biases as we tend to perceive AI algorithms as impartial and secure, though these algorithms are trained by humans (Vicente & Matute, 2023).

6.2 Ethical and Legal Implications

The issue of accountability in AI-assisted OSINT investigations is complicated by unclear regulations and shared responsibility among users, developers, and data providers. This makes it difficult to verify decisions and assign blame, particularly when errors adversely affect individuals or resources (Alnaqbi, 2025). AI stakeholders include users, platform providers, and AI developers. Prompt and session histories are examples of digital evidence that must be collected using novel investigative techniques to demonstrate both intent and the role of AI in decision-making (Karakikes & Kotis, 2025). Assigning responsibility for errors made by AI during investigations remains a significant challenge. Moreover, the widespread use of OSINT raises privacy concerns due to the large volumes of personal data collected from social media, potentially leading to violations of human rights. There is also a risk of algorithmic bias in information processing, highlighting the need for stronger regulations and ethical assessments of AI use in military and intelligence contexts (Meng, 2025).

Managing accountability for investigative errors in AI-assisted OSINT requires a systematic approach that emphasizes human oversight and the development of validated OSINT frameworks (OSINT-V). Human analysts bear the primary responsibility, as their expertise is essential in distinguishing accurate data from erroneous outputs produced by AI. They play a critical role in mitigating hazards such as false positives, which can be exacerbated by data sparsity or unreliable sources (Alturkistani & Chuprat, 2024). Integrating interpretable models with explainable AI (XAI) further enables analysts to understand the reasoning behind automated decisions, such as categorizing complex attack stages or identifying illicit botnet activity.

7. Recommendations for OSINT Investigators

Effective OSINT investigations require not only technical skills but also structured methodologies, ethical awareness, and the ability to critically evaluate sources. Based on the challenges and opportunities identified in the previous sections, this section provides practical recommendations, summarised in Table 2, to enhance the reliability, efficiency, and ethical integrity of OSINT operations.

Table 2: Recommendation Summary

Recommendation	Key Actions	Purpose / Benefit
Integrate LLMs as Analytical Assistants	Use LLMs to summarize and analyse large data sets; retain human oversight	Enhances efficiency while reducing risks of hallucinations or bias
Rigorous Verification & Validation	Cross-check multiple sources; use fact-checking tools; document verification	Ensures accuracy, reliability, and transparency of findings
Structured Investigation Workflow	Apply frameworks like ORS; define clear objectives	Organizes tasks, reduces cognitive load, and improves investigation focus
Responsible Use of OSINT Tools	Utilize Shodan, Censys, Fofa, VirusTotal, IPInfo; comply with legal standards	Identifies threats efficiently while maintaining ethical compliance

Recommendation	Key Actions	Purpose / Benefit
Monitor & Mitigate AI Risks	Audit LLM outputs; implement human-in-the-loop reviews	Maintains data integrity and reduces errors from AI outputs
Ethical & Legal Compliance	Respect privacy laws, IP rights, and local regulations; develop ethical guidelines	Protects investigators and organizations from legal and reputational risk
Documentation & Transparency	Record all sources, methods, and analytical decisions; note limitations	Supports accountability, traceability, and reproducibility

These recommendations, collectively presented in Table 2, aim to ensure that OSINT investigations are accurate, efficient, and ethically responsible, while fully leveraging the analytical power of LLMs without compromising reliability or compliance. They also outline strategies for integrating LLMs into investigative workflows, ensuring rigorous verification of findings, mitigating AI-related risks, and adhering to legal and ethical standards. By following these recommendations, OSINT investigators can maximize the value of publicly available information while minimizing errors, biases, and potential ethical violations.

8. Conclusion

This study evaluated the performance of eight LLMs in conducting OSINT investigations, using a synthetic case study of the fictional CtrlZ Society. The results demonstrate that LLMs possess considerable potential as analytical assistants, capable of synthesising information, reconstructing timelines, attributing accounts, and maintaining evidence traceability. Models such as Claude 3, GPT, Meta, and Qwen 2.5 performed particularly well, highlighting the capacity of advanced LLMs to enhance efficiency and support complex investigative workflows. At the same time, the study revealed important limitations and risks. Some models exhibited tendencies toward forced narrative construction and overreach beyond the provided data, while all LLMs remain constrained by the scope and recency of their training data. The potential for errors, misinterpretation, and susceptibility to adversarial prompts underscores the necessity of human oversight, methodological safeguards, and continuous validation when integrating LLMs into OSINT workflows.

In summary, LLMs should be viewed as collaborative tools rather than autonomous investigators. They can act as a valuable friend when leveraged responsibly, but they can also become a foe if relied upon without critical evaluation. The findings underscore the importance of combining human expertise with LLM capabilities, ensuring that OSINT investigations remain accurate, reliable, and ethically responsible. Future research should focus on developing robust evaluation frameworks, refining safeguards against bias and misinformation, and exploring best practices for responsible LLM deployment in intelligence contexts.

Ethics declaration: Ethical clearance was not required, as this study did not involve human participants.

AI declaration: AI, specifically eight LLMs, were utilised in this study, as indicated in the methodology section.

Expanding Tactical Cyber Operations for Information-Age Warfare

Archie Bass and Timothy Shives
Naval Postgraduate School, Monterey, California, USA

archie.bass@nps.edu
timothy.shives@nps.edu

Abstract: The proliferation of information through cyberspace has reshaped the character of modern warfare and altered how power is generated and exercised. Digital systems now underpin intelligence collection, operational coordination, and influence activities across instruments of national power. This dependence creates a persistent capability–vulnerability paradox in which the same networked systems that provide operational advantage also introduce exploitable weaknesses. Although the United States has developed significant strategic cyber capabilities, operational authorities and execution remain largely centralized. Incident data show that espionage, access operations, and information manipulation dominate cyber-conflict patterns, while bespoke cyber tools remain constrained by access requirements, target specificity, and limited reuse. This paper argues that maintaining an advantage in the information age requires expanding cyber execution capability and selected authorities to operational and tactical levels. It examines how cyber power's low barrier to entry enables both state and non-state actors to generate disproportionate effects and how cyberspace, as a human-built domain, often favors offense over defense. The study outlines limits on the employment of strategic cyber tools, including tradeoffs among speed, intensity, and control, as well as the single-use nature of exposed exploits. The paper proposes a tactical cyber operations framework built on dispersed, hyper-enabled units operating under decentralized command and supported by operational-level artificial intelligence processing and human–machine teaming. The framework integrates distributed intelligence validation, signature reduction, deception and decoy practices, and ambiguity operations designed to slow adversary decision cycles and increase targeting uncertainty. The paper concludes that doctrinal and authority structures should evolve to support delegated cyber action aligned with the commander's intent in persistent cyber competition.

Keywords*:* Tactical cyber operations, Cyber power, Decentralized command, Human–machine teaming, Cyber deception, Distributed operations

1. History of Information and the Importance of Cyberspace

The proliferation of information through cyberspace has fundamentally reshaped the character of modern warfare. Cyberspace expands information access to remote users and "may prove as valuable and influential in the post-industrial era as capital and labor have been in the industrial age" (Arquilla and Ronfeldt, 1993). Information technology, which enables access to information through cyberspace, is inseparable from modern warfare and generates a persistent capability/vulnerability paradox (Schneider, 2019). This paradox, combined with the inherent security weaknesses of cyberspace, creates enduring opportunities for exploitation across strategic, operational, and tactical levels of warfare. The United States has leveraged these opportunities through cyber operations; however, early efforts remained primarily confined to the strategic level due to personnel and equipment constraints. Over time, the sophistication and quantity of trained personnel and equipment have increased, yet cyber operational authorities have largely remained centralized at the strategic level. Cyber actors rely on cyberspace to rapidly transfer, aggregate, and collect information. The adversary's dependence on cyberspace to conduct operations, coupled with cyberspace's inherent characteristics and security weaknesses, necessitates that the United States delegate cyber authorities and operational approval down to the operational and tactical levels to maintain an advantage in this dynamic, evolving domain.

Organizations, whether nation-states or non-state actors, invest their limited resources to increase their relative power and to exert influence on external actors to secure resources and achieve their organizational goals (Nye Jr., 2010). Cyberspace enables access to and exploitation of information, both of which are fundamental to the use of power (Nye Jr., 2010). Organizations utilize cyberspace as a unique opportunity to rebalance power and increase influence in the information age.

Cyber power—"the ability to use cyberspace to create advantages and influence events in all operational environments and across the instruments of power"—has a relatively low barrier to entry because the required assets and training are readily available on the open market (Kramer, Starr and Wentz, 2009). Moreover, cyber power requires significantly fewer resources than developing other types of power, such as a naval fleet or a nuclear weapons capability. This smaller resource requirement allows nearly any organization to wield substantial cyber power worldwide. Cyber power is distinctive because actors can use it across the spectrum of diplomatic, informational, military, economic, financial, intelligence, and law-enforcement (DIME-FIL) domains. This unique ability to produce widespread effects stems from each DIME-FIL instrument's dependence on cyberspace. As a result, organizations can acquire and project extensive cyber power with relatively modest

investments. This incentive has flooded cyberspace with a variety of actors, leading to a broad distribution of power, although not absolute equality. Such a distribution diminishes the control traditionally held by superpowers over domains like the air and the sea. The increasing use of cyberspace also introduces a capability/vulnerability paradox, which makes exploitation across different levels of warfare more possible. (Schneider, 2019).

In the early 2010s, terrorist organizations quickly adapted to the changing information environment, gaining significant cyber power with minimal investment. In July 2015, Ayman Al Zawahiri stated that al-Qaeda was in a "battle and more than half of this battle is taking place in the battlefield of the media" (Kapsokoli, 2019). Terrorist organizations like al-Qaeda understood that this new cyberspace environment was critical to controlling the narrative and influencing the population. Terrorist organizations also use the fast, reliable, and ambiguous nature of cyberspace to conduct mission planning and coordination. (Kapsokoli, 2019). These communication pathways also assist with identifying, radicalizing, and recruiting susceptible individuals (Kapsokoli, 2019). Terrorist organizations then instruct recruits through a virtual training camp that teaches them how to plan, prepare, and conduct terror attacks (Kapsokoli, 2019). Terrorist organizations also use cyberspace and cryptocurrencies to collect and transfer funds without interference from organizations like the FBI. Finally, cyberspace allows terrorists to spread terror through the amplification of their desired narrative to a level that was unimaginable before social media. Because of their limited resources and high adaptability, terrorist organizations were among the earliest adopters of cyberspace and have leveraged it to exert disproportionate influence.

Cyberspace is a unique domain, as it is a "flexible, human-built, institutionally governed, sociotechnical infrastructure" that favors offensive actions over defensive posture (Lindsay and Gartzke, 2022). Being the only human-built domain (the other domains are maritime, land, air, and space), cyberspace presents distinct opportunities for users. For example, cyber operators can exert cyber power to "produce preferred outcomes within cyberspace, or [they] can use cyber instruments to produce preferred outcomes in other domains outside cyberspace" (Nye Jr., 2010). These subsets are referred to as intra-cyberspace power and extra-cyberspace power, respectively (Nye Jr., 2010). Both of these subsets favor offensive over defensive cyber power (Arquilla, 2021). This offensive advantage is rare within warfare, where defense is typically the dominant form. These conditions enable the evolution of cyberspace attacks from isolated incidents to "coordinated, multi-domain military operations" (Devanny, Goldoni and Medeiros, 2022).

The integration of artificial intelligence (AI) into cyberspace will improve both offensive and defensive cyber capabilities. However, AI is likely to further enhance offensive advantages. Cyber actors use AI to amplify their effects both within and outside cyberspace. In 2022, a U.S. intelligence review found that Russia had invested over $300 million in foreign influence campaigns over the past eight years. Although the success of these investments varies, the substantial Russian investment highlights the strong link between cyberspace, artificial intelligence, and information operations. Russia also employs cyber operations against targets beyond cyberspace. In December 2015, the BlackEnergy malware caused power outages that affected over 230,000 people in Ukraine. Additionally, in 2017, the NotPetya attack on a Ukrainian bank spread worldwide and caused roughly $10 billion in damages. These attacks demonstrate the destructive potential of cyber operations that extend beyond cyberspace, butactors planning to seize infrastructure should avoid causing irreversible damage. For example, when Russia invaded Ukraine in 2022, the aim was to seize critical infrastructure intact, particularly the communications network, to ensure its continued usefulness for the invaders. Destroying the communications network would aid current military operations, but it would also require additional effort and money to restore it afterward. On the other hand, this choice to limit attacks on critical infrastructure allowed Ukrainian forces to keep using it for defense. When choosing cyber targets that extend beyond cyberspace, actors must balance the immediate military benefits against possible long-term effects. These structural dynamics shape not only the strategic environment but also the operational constraints under which cyber power is developed and employed.

2. Cyber Tool Constraints and Strategic–Operational Imbalance

Cyberspace also presents distinct challenges because three key variables—speed, intensity, and control—negatively correlate with one another, and cyber tools lack universal effectiveness (Maschmeyer, 2021). Both intra- and extra-cyberspace powers depend on access and require a bespoke cyber tool tailored to the specific target (Borghard and Lonergan, 2019). This access, along with the tool's required specificity, limits its fungibility. This limitation is compounded at the strategic level because access is drastically more resource-intensive to gain and maintain. Additionally, the time required to develop the cyber tool, the extent of its impact, and the ability

to control its effects once deployed are in direct competition with one another, creating the "subversive trilemma" (Maschmeyer, 2021). Finally, once organizations develop a strategic tool and the opportunity to employ it arises, commanders face the reality that "cyber operations have a 'use it and lose it' quality" (Borghard and Lonergan, 2019). This single-use nature of the cyber tool stems from its bespoke design. Once the exploit is exposed, it can be patched with relative ease. The United States' decision-makers have seldom employed strategic cyber power because it has limited applicability, and they are reluctant to expend a capability they may need in the future.

The discussion of the importance of cyber access for power projection gave rise to cyber persistence theory (CPT). CPT posits that for a state to achieve security in the cyber strategic environment, it must maintain constant contact with the adversary (Fischerkeller *et al.*, 2022). This differs from traditional international relations (IR) theory, in which physical barriers limit the projection of power, and peace is the absence of interaction (Akdağ, 2025). CPT provides an alternative approach to deterrence that does not require confrontation in the physical domain and limits the risk of escalation in the nuclear environment (Fischerkeller *et al.*, 2022).

Although the United States focuses on strategic cyber operations, the Dyadic Cyber Incident and Campaign (DCID) dataset 2.0 found that 61% of cyber incidents since 2000 have been cyber espionage operations (Maness *et al.*, 2023). This emphasis on cyber espionage also bears true during full-scale conflict. Between January 2022 and August 2023, the two most common categories of cyber incidents in Ukraine were malicious code (11%) and espionage (7%) ("A Decade in the Trenches of Cyberwarfare: Ukraine's Story of Resilience," 2024). Additionally, the premier Russian cyber operators work within departments that specialize in intelligence and subversion (Giles, 2023). The United States will continue to cede power and influence if it does not begin to prioritize the ongoing cyber competition for the collection and manipulation of information and data (Cristiano *et al.*, 2023).

Russia does not distinguish between the information domain and information operations; instead, it considers information as "the tool, the environment, and the target" (Giles, 2023). Between 2013 and 2021, this integrated understanding allowed Russian cyber operations to experience a "strategic shift from opportunistic disruption to calculated, long-term planning," aligning with Russia's broader geopolitical strategy ("A Decade in the Trenches of Cyberwarfare: Ukraine's Story of Resilience," 2024). Russia has also effectively integrated cyberspace into its long-standing Soviet-era doctrine of disinformation tactics and manipulation of public perception, yielding significant effects in the information environment ("A Decade in the Trenches of Cyberwarfare: Ukraine's Story of Resilience," 2024). Russia uses its Internet Research Agency, also known as a "troll farm," to further its information campaign by disseminating disinformation and manipulating the narrative ("A Decade in the Trenches of Cyberwarfare: Ukraine's Story of Resilience," 2024). Russia also tolerates pro-Russian hacktivist groups, such as Killnet, Xaknet, and NoName057, to conduct distributed denial-of-service (DDoS) attacks, thereby removing direct attribution ("Chronology of Cyber Aspects of the war in Ukraine 2022–Present," 2024). Additionally, Russia conducts cyber espionage operations on Western countries to gather information related to the Ukrainian security assistance strategy. ("Chronology of Cyber Aspects of the war in Ukraine 2022 – Present," 2024). Lastly, Russia often employs cyber to shape the physical and information environment for future kinetic operations ("Chronology of Cyber Aspects of the war in Ukraine 2022–Present," 2024; "A Decade in the Trenches of Cyberwarfare: Ukraine's Story of Resilience," 2024). These various tactics are subsets of a coordinated and integrated approach that is only possible because of Russia's comprehensive understanding of cyberspace, information, psychological operations, and narrative control.

Although Russia has taken a comprehensive approach to cyber operations, its efforts have often been countered effectively by Ukrainian civilian and government countermeasures supported by an international coalition. On February 26, 2022, two days after Russia's invasion, Ukraine announced the formation of an "IT Army" and called for talented applicants to join. That same day, Ukraine assigned initial tasks to this group to carry out a DDoS attack on selected Russian commercial and government websites. The Ukrainian IT Army quickly gained hundreds of thousands of followers worldwide, making it resilient to attacks. Molfar, a private Ukrainian company, uses open-source intelligence to collect target-quality data from social media posts and supplies it to Ukrainian Intelligence for operational use. Ukraine's cyber defenses have received international support through direct cybersecurity assistance and cyber intrusion alerts. The combination of civilian and government capabilities, bolstered by international advice and aid, has enabled Ukraine to neutralize Russia's credible cyber threats and directly support its kinetic defense operations.

As cyberspace becomes increasingly integrated into daily life, its prominence and society's reliance on information will continue to grow. The organizations that can rapidly adapt and gain relative cyber power will exert unmatched dominance across all warfighting domains and instruments of power. The deterrent role of

strategic cyber power is essential and should be maintained. However, limiting cyber capabilities to the strategic level unnecessarily constrains the United States. Therefore, the United States should expand the employment of cyber power to the operational and tactical levels to increase tempo and gain a significant advantage over threat actors.

3. Tactical Cyber Operations and Distributed Execution

The information revolution will continue to expand cyberspace's availability to more organizations, groups, and people. As cyberspace becomes increasingly integrated into daily life, organizations will become increasingly dependent on it (Mbanaso and Dandaura, 2015). This dependence spans the range from daily administrative tasks to the development and employment of the most exquisite instruments of national power. This reliance intensifies the capability/vulnerability paradox and creates expansive opportunities for exploitation (Schneider, 2019). The United States should employ dispersed, hyper-enabled teams with the necessary authorities and permissions to leverage tactical cyber operations to "swarm" adversary threats, thereby meeting the commander's intent through decentralized command (Arquilla, 2021).

Successful military operations have always relied upon developing trustworthy information into actionable intelligence. To complete this, analysts gather information through the seven intelligence disciplines: human intelligence (HUMINT), geospatial intelligence, signals intelligence, measurement and signature intelligence, open-source intelligence, technical intelligence, and counterintelligence (U.S. Joint Chiefs of Staff, 2013). Following the collection, this information is synthesized and published as intelligence for further use. Beyond HUMINT, each of these disciplines relies heavily on capabilities that reside in cyberspace. Therefore, the actual battle is a fight for critical pieces of information in cyberspace. In the information age, more information is available than can be analyzed, which is where the need for dispersed, hyper-enabled teams emerges. To succeed in information warfare, tactical units must possess both the capability and authority to rapidly transition from gathering information to executing operations, thereby ensuring they capitalize on the information advantage before it becomes obsolete.

Cyberspace has, however, also expanded the availability of fake and misleading information. Cyberspace enables actors to fabricate massive amounts of information, thereby decreasing the reliability of various sources and source types. This concern has altered the intelligence cycle and increased the quantity of analysis required. To validate the integrity of the information, analysts must understand the reliability of the data source and verify its authenticity by corroborating it across multiple sources and over time. Additionally, the time required to make this interpretation increases as the analyst becomes further removed from the source. Accordingly, the United States must deploy the appropriate personnel at the appropriate echelon to conduct this analysis in close proximity to the information source. Expanding tactical cyber capacity, however, requires analytic scalability to manage the volume and velocity of contested information.

4. Artificial Intelligence and Human–Machine Teaming

The information access provided by cyberspace, coupled with advanced information technologies, has inundated analysts with an abundance of available information. Although human input will always be necessary, analysts should deliberately shift a portion of this analysis to AI engines; this pairing of AI models with humans is often referred to as a human-machine team (HMT). AI systems can efficiently ingest, categorize, and structure large-scale data streams, ensuring that "information is made swiftly available to forces operating at the leading edge of battle" (Arquilla, 2021). However, as these AI models develop through machine learning, they will inherently absorb biases and begin improperly connecting information to create a narrative. Analysts should transition from brute-force analysis of raw data to dissecting and validating the narrative generated by the AI engine. This verification process will ensure that the AI models do not devalue or over-rely on critical pieces of intelligence. Operational-level commands should conduct AI processing because they possess the required power, connectivity, and force protection measures. Additionally, operational-level commands have access to additional information systems. The operational commands can transmit the parsed intelligence to the tactical level for verification and immediate operational use. The employment of HMTs, combined with task delineation across command echelons, will expedite analysis and ensure the prompt execution of actionable intelligence.

Machine learning models, a subcategory of artificial intelligence, predict outcomes by learning from data and building synthetic models. These models perform best when employed in the same context in which they were trained. After training, they cannot operate independently and are most effective with human oversight. At the operational level, these models can be integrated with analysis teams to expedite the process and reduce the time required to produce each intelligence report. These reports can then be distilled and communicated to

tactical forces for implementation. The military's use of AI must account for increased risks and changing operational dynamics. For instance, Denise Garcia and the Committee on Human-System Integration at the Air Force Research Lab have warned that AI models can produce unpredictable and sometimes misleading results, posing significant concerns for the military. Another key consideration is that adversaries can manipulate the data used for training and analysis to deceive or confuse the models. This vulnerability means the models must be safeguarded against external influences and be completely transparent about how and why they arrived at their outcomes. The military's deployment of AI naturally extends its capabilities and can support cyber operations when used responsibly to augment, not replace, human decision-makers. The integration of AI-enabled analysis must therefore be paired with force architectures designed for survivability and resilience.

5. Dispersed Units, Signature Reduction, and Survivability

The information age has also created a dependence on rapid, reliable communication and connectivity. This reliance has amplified the technical signature of tactical units and decreased their survivability. To counter this phenomenon and reduce this vulnerability, the United States should employ small, dispersed units of action capable of coordinating and massing fires against the enemy (Arquilla, 2021). The decrease in unit size will reduce external communication and allow for tightly controlled internal networks. Reducing the size of each unit diminishes its technical signature and enhances cybersecurity by limiting the number of users who require network access. These units' reduced physical and technical signatures mitigate initial force protection concerns associated with their smaller size. The reduced user demand per location also enables enhanced cybersecurity measures, thereby reducing the threat of cyber infiltration and exploitation. Additionally, the dispersed units provide additional collection opportunities from their distributed locations. This approach should serve as the primary method of employment until the next significant disruption to the information environment. The integration of AI-enabled analysis must therefore be paired with force architectures designed for survivability and resilience.

6. Deception, Decoys, and Ambiguity Operations

An additional mechanism to mitigate force-protection concerns for small, dispersed units is to employ deception tactics. For example, through an in-depth understanding of Russian targeting, Ukraine has employed decoys, such as inflatable tanks and flat-pack artillery, to mimic high-value targets that then received live Russian ordnance (Shevchenko, 2025). With minimal investment, this tactic can drastically increase the cost for an adversary and erode trust in its intelligence reports, thereby slowing the targeting cycle (Fowler and Nesbit, 2013). Finally, the use of decoys can mislead foreign intelligence to the location of pending attacks, thereby increasing operational success. In an era where being sensed is tantamount to being targeted, the United States should invest in a similar decoy capability to deceive the enemy of our intentions and enhance the survivability of tactical units.

Although the physical deception tactics described above are valuable in the physical domain, they do not reflect the intricacies of deception in the virtual environment. Due to the interconnectedness of today’s operating environment, a recent emphasis in military practices has been on synchronizing effects across domains. Multi-Domain Operations requires the orchestration of military and non-military activities across all domains (Land, Sea, Air, Space, Cyber) to create desired outcomes in space and time (NATO’s Strategic Warfare Development Command, 2023). Current deception theories, however, lack the complete integration of the cognitive, physical, and virtual dimensions, with many describing the virtual as merely a channel rather than a core component (Grant and Henderson, 2025). Even newer cyber-specific deception theories, such as those of Rowe and Rrushi (2016), misidentify the target as the machine and lack the evaluation required to holistically determine the effects of deception in an MDO context. Finally, further research is required to determine appropriate measures of effectiveness for virtual deception operations.

Another method for reducing force protection concerns is by dispersing units of action across the battlespace. This tactic also enables the rapid dissemination and execution of critical intelligence across both physical and cyberspace domains. These units can analyze AI-derived information and share key intelligence via low-probability-of-intercept and low-probability-of-detection communications with lateral units. This form of communication is preferred for its reduced signature, though it is constrained by limited data transmission capacity. However, each unit's intelligence and cyber personnel can address this limitation by distilling the data before transmission. This low-signature tactical communication and coordination technique, coupled with each unit's ability to conduct physical and cyberspace operations, will considerably increase force protection.

The United States also needs to take specific actions inside and outside cyberspace to increase ambiguity for an enemy decision-maker or reduce ambiguity by misleading their decision-making process into a favorable outcome (Daniel and Herbig, 1982). To increase ambiguity, the United States should vary the technical signatures of its locations and deploy decoy emulators at unused sites. These emulators are most effective when used in conjunction with visible decoys to further deceive adversarial sensors. AI bots at these sites could simulate electronic communications by emitting appropriate signatures. By increasing ambiguity (A-type), the United States will confuse the enemy about the location of its actual forces, requiring the adversary to spend time and resources confirming each location (Daniel and Herbig, 1982). These actions will also enhance force protection at each active site. Additionally, the tactical units should decrease ambiguity and mislead the adversary (M-type) by seeding misinformation about their intent and capabilities (Daniel and Herbig, 1982). These actions should be controlled and approved at the tactical level to increase their tempo and decrease communications with higher commands. By varying the level of ambiguity, these dispersed units can immobilize the adversary decision-maker and increase operational effects across the battlespace. The resulting surprise has been shown to increase casualties for the adversary while decreasing casualties for the initiator (Whaley, 2007). Operationalizing these capabilities at scale ultimately requires institutional adaptation in doctrine, authority structures, and campaign design.

7. Conclusion - Doctrine, Authority, and Implementation Implications

In conclusion, information will continue to play a vital role in military operations throughout the 21st century as more daily activities become dependent on cyberspace. Cyberspace has dramatically transformed modern warfare, and rapid adaptations are necessary to maintain the United States' military dominance. The United States has become increasingly reliant on large bases with extensive personnel and communications equipment, which enable real-time, direct links to tactical units. The United States must rethink how it conducts warfare and become comfortable with limited communications, giving tactical commanders the decision-making space to seize real-time opportunities. The United States should employ AI-enabled operational commands and deploy small, dispersed, hyper-enabled tactical units. These commands will quickly process vast amounts of information and deliver actionable intelligence to tactical units. The tactical units will stay below detection thresholds while validating intelligence and executing operations swiftly and efficiently. These strategies incorporate ten principles from Arthur Buckley's book, "Principles and Deceptions," and complicate the adversary's decision-making process. As AI advances, it will deepen human reliance on cyberspace. Commanders should leverage this dependency by deploying tactical units with the necessary authorities to address vulnerabilities and align with strategic objectives, ensuring operational success in the information age. The United States Department of War must update its joint doctrine to implement these techniques effectively. This revision must consider how cyberspace has altered traditional views of the competition continuum. A conventional framework that classifies interactions between states as cooperation, competition, or conflict no longer fully captures the kinds of hybrid and information warfare tactics that Russia has effectively utilized throughout the 21st century. Armed with this perspective and the outlined techniques, the United States strengthens its ability to maintain military advantage in the information age.

A Lightweight Real-time Framework for Detecting Rogue Switches in Wired Local Area Network

Vijay Bhuse, Vijay Prathap, Reddy Kanipakam and Xinli Wang

wangx@gvsu.edu

Abstract: In today's digital landscape, securing wired network infrastructure is essential, particularly for Small and Medium Enterprises (SMEs) that often lack dedicated security personnel and resources. This project presents a fully automated, cost-effective method for detecting rogue switches, which are unauthorized devices that may be introduced by malicious insiders or external attackers to bypass network controls. Unmanaged (dumb) switches facilitate lateral movement, network sniffing, and long-term persistence, allowing adversaries to blend into legitimate traffic without detection. To counter this threat, the proposed system employs a correlation-based detection mechanism, supported by a three-layer validation model, to systematically verify infrastructure changes. The layered design reduces false positives and ensures accurate identification of unauthorized network modifications. Tailored for SME environments, this solution removes the need for manual inspection, offering a scalable, real-time response to rogue switch detection and mitigation.

Keywords: Rogue switches, Open vSwitch (OVS), Topology monitoring, ARP-scan, fping, MAC and ARP spoofing, SMTP alerts

1. Introduction

Wired Local Area Networks (LANs), though often perceived as inherently secure, are increasingly exposed to internal threats that bypass traditional perimeter defences. Among the most critical of these threats is the introduction of rogue switches, unauthorised Layer 2 devices silently connected to existing infrastructure. These unmanaged switches are typically plug and play, and lack visibility in network management systems.

Once connected, rogue switches enable adversaries to passively attach multiple devices, sniff traffic, or launch cyberattacks, all while blending into legitimate network activity. This allows attackers to bypass authentication controls, intercept sensitive data, and maintain persistent access within the network environment.

As enterprise networks grow in complexity, for SMEs with limited security infrastructure, the challenge of detecting such hidden threats becomes even more critical.

To address this, the proposed work introduces a structured rule-based detection framework that identifies rogue switches through layered validation focused on topology changes, device registration, and spoofing behavior. This real time, vendor neutral solution is scalable, lightweight, and does not require proprietary hardware, making it suitable for SMEs that need practical and reliable security mechanisms.

2. Related Work

Rogue switches in wired Local Area Networks (LANs) present a persistent challenge due to their passive nature and limited traceability. These unmanaged devices typically lack routable identities and do not participate in Layer 2 discovery protocols such as Link Layer Discovery Protocol (LLDP) or Cisco Discovery Protocol (CDP), rendering them invisible to conventional monitoring tools.

Several approaches have been proposed to infer their presence. Port-security controls such as BPDU Guard and PortFast are widely used to protect against unauthorized switches by disabling ports that receive unexpected Bridge Protocol Data Units (BPDUs) [1] (2024). However, these safeguards assume protocol participation. Unmanaged "dumb" switches neither emit BPDUs nor respond to LLDP or CDP, and can therefore forward traffic silently. In enterprise settings, comprehensive Network Access Control (NAC) commonly incorporates IEEE 802.1X [2] (2020) for port-based admission (EAP over LAN to a RADIUS backend), together with device profiling, posture assessment, and policy-based VLAN/ACL assignment. While NAC/802.1X is effective at deciding who may access a port and enforcing policy at admission time, it does not continuously validate post-admission physical changes or reveal hidden fan-out; a transparent unmanaged switch can still be placed behind an already authenticated port. The method proposed here is complementary; it supplies post-admission visibility that protocol-triggered controls and NAC do not provide.

Anomaly-driven studies have looked at access-segment signals and Layer 2 controls in lab settings. Bhuse et al. [3] (2025) combined management plane telemetry with Dynamic ARP Inspection, DHCP Snooping, Root Guard,

and Port Security with Sticky MAC in a GNS3 and Cisco setup, and added a supervised logistic regression model. The results were strong for ARP spoofing, MAC flooding, and STP root manipulation, but the pipeline was evaluation-focused, dependent on specific vendors, and not run as an always-on alerting service. Bhuse and James [1] (2020) used SNMP broadcast-storm traps as the initial signal, confirmed activity with ARP probes and announcements, and traced offenders using the router ARP table and switch CAM tables. Quitiquit and Bhuse [2] (2022) watched link state and MAC table activity to infer downstream insertion. In practice, these methods can miss short-lived events because of polling intervals, assume uniform management access and credentials across devices, and require manual playbooks or vendor-specific tooling. They also provide limited correlation across signals after admission, which can increase false positives or delay detection when changes are subtle or brief.

Most existing strategies address individual behaviors or require specific infrastructure. They do not offer a unified, vendor-neutral process that adapts across network conditions, especially in resource-constrained environments. This paper introduces a lightweight, rule-based detection framework that continuously validates physical topology changes, verifies registered devices, and detects spoofing behavior in real time. The rules and the correlation logic are configurable, so organizations can tune thresholds, whitelist known infrastructure, and add or remove checks to match their topology and policy. By maintaining a simple topology and MAC–IP baseline, performing active discovery from a trusted host, checking ARP consistency to spot impersonation, correlating signals to reduce noise, and emailing administrators immediately when something new or suspicious appears, the framework offers a practical and scalable option for SMEs.

3. Problem Statement

Existing solutions for detecting rogue switches often rely on proprietary protocols, manual tracing, or SNMP-based infrastructure, which are not always practical in real-world SME environments. Unmanaged switches that do not participate in discovery protocols can silently forward traffic, bypassing traditional security controls. In practice, budget constraints often lead to the deployment of low-cost, Fast-Ethernet unmanaged switches, further reducing protocol visibility and complicating detection. There is a need for a lightweight, rule-based detection framework that can identify such devices in real time without relying on complex infrastructure or protocol-level visibility.

4. Proposed Solution

The proposed framework enables real-time detection of rogue switches in wired LAN environments through a layered validation approach. It incorporates topology monitoring, device verification, and ARP cache analysis to detect unauthorized links, unregistered devices, and address spoofing. A trusted baseline of active authorized switch-port mapping and as well as MAC–IP mapping for Compliant (authorized) devices, is maintained and periodically compared against live network data. Upon identifying anomalies, the system triggers alerts via an SMTP-based notification mechanism.

To ensure long-term accuracy and compliance with organisational network governance standards, baseline updates are strictly manual and subject to predefined security policies. This approach minimises false positives while preserving the integrity of the detection process.

5. Implementation

The framework was implemented using Ubuntu, Mininet, Open vSwitch, and Bash scripting to define detection rules and automate topology monitoring. OVS (Open vSwitches) were monitored to detect topology changes and unauthorised links, while tools such as fping and arp-scan were integrated for active scanning and host discovery. ARP cache analysis was used to detect MAC and IP spoofing attempts. Postfix was configured to handle SMTP-based alerting. This approach is vendor-independent, lightweight, and suitable for real-time rogue switch detection..

5.1 Topology Overview

The test environment was configured to simulate a realistic enterprise LAN structure using Mininet's tree topology. The network consists of one core switch (s1) connected to four access-layer switches (s2 to s5). Each access switch is linked to four hosts, resulting in a total of sixteen hosts (h1 through h16). Specifically, s2 connects to h1 to h4, s3 to h5 to h8, s4 to h9 to h12, and s5 to h13 to h16. This topology emulates a structured multi-segment LAN, enabling detailed analysis of rogue switch insertion, spoofing behaviour, and automated alert

generation across various zones. Each detection rule was tested individually to evaluate the accuracy and responsiveness of the framework.

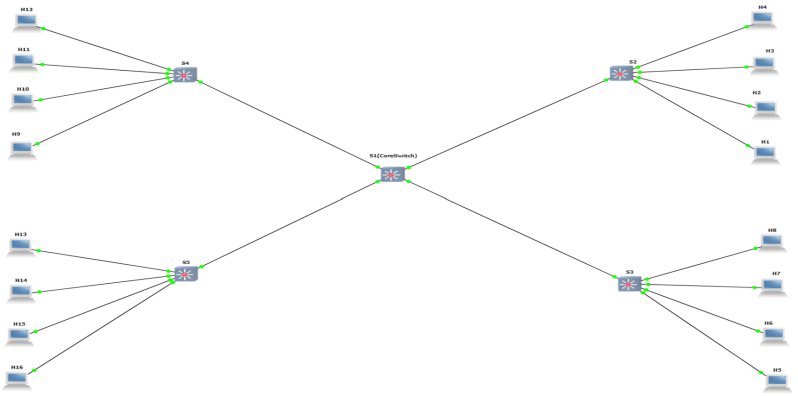

Figure 1a: Topology

5.2 Detection Rules Overview

Before introducing any rogue elements, the detection framework establishes a secure and trusted view of the network using three-layered rules. These rules work together to ensure that any unauthorised or malicious changes are promptly identified.

Rule 1: Topology Change Detection

Open vSwitch (OVS) is used to monitor the real-time status of switch ports. OVS listens to kernel-level network events such as cable insertions/removals, interface state changes, or system configuration updates. These events are reflected instantly in the OVS database and can be queried using ovs-vsctl show.

Once the network stabilises, a baseline snapshot of all switch-port mappings is taken and saved as baseline_topology.txt. This serves as a trusted reference, and the script periodically compares it against the current topology every few seconds to identify any unauthorised modifications (e.g., newly added ports from rogue switches to further connect multiple devices using a single legitimate switch port).

Open — baseline_topology.txt — ~/Desktop/Topology change script

```
1 Switch: s3
2   Port: s3-eth5
3   Port: s3-eth2
4   Port: s3-eth4
5   Port: s3-eth1
6   Port: s3-eth3
7 Switch: s2
8   Port: s2-eth2
9   Port: s2-eth4
10  Port: s2-eth1
11  Port: s2-eth3
12  Port: s2-eth5
13 Switch: s4
14  Port: s4-eth3
15  Port: s4-eth2
16  Port: s4-eth1
17  Port: s4-eth5
18  Port: s4-eth4
19 Switch: s1
20  Port: s1-eth4
21  Port: s1-eth2
22  Port: s1-eth3
23  Port: s1-eth1
24 Switch: s5
25  Port: s5-eth5
26  Port: s5-eth3
27  Port: s5-eth2
28  Port: s5-eth4
29  Port: s5-eth1
```

Figure 1b: Switch Active Ports (Baseline)

Rule 2: Device Registration and MAC Mapping

After establishing the baseline switch-port topology, the second rule focuses on identifying all active end devices and registering their corresponding MAC and IP addresses. This rule ensures that only legitimate hosts are recognised before the detection framework begins operation.

The system initiates a fast subnet-wide sweep using fping, which sends ICMP echo requests across the network to detect live hosts. Once responsive hosts are identified, tools like arp-scan or arping are used to send ARP

requests, forcing those hosts to reply with their MAC addresses. This process creates a reliable IP–MAC mapping for every connected device in the network.

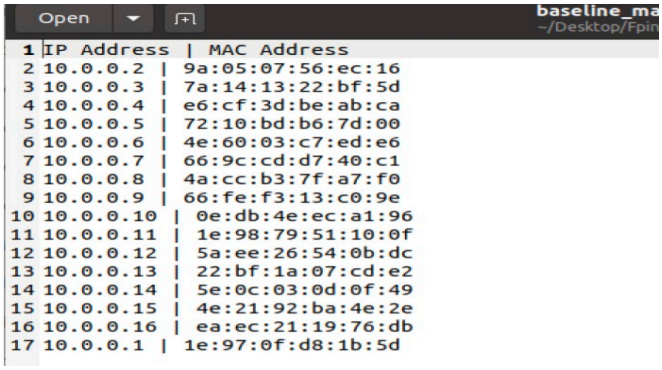

Figure 2: Trusted MAC–IP

To ensure trust and consistency, this scan is executed from a known legitimate host (h1), connected to access switch s2. Scanning from within a trusted network segment minimises the risk of spoofed replies or detection evasion by rogue nodes.

The resulting mappings are stored in a reference file named baseline_mac_ip.txt. This file acts as the foundation for all runtime MAC address verifications. During monitoring, any MAC address not found in this baseline is flagged as a potential rogue device.

The baseline can be updated when new, authorised devices are introduced. Each update must include the device's MAC address and its active switch port connection at the time of registration. For DHCP environments, detection keys are used for MAC-first matching. IP changes are tolerated, but MAC–IP conflicts and unknown MACs still trigger verification and alerts.

However, to ensure the security integrity of the framework, all baseline modifications must be manually approved in accordance with internal policies. This prevents accidental or malicious whitelisting of unauthorised devices.

During detection, any new MAC address not present in the baseline is treated with high priority, as it may indicate the presence of a rogue switch introducing new connected hosts. The severity of the alert increases if this MAC anomaly is accompanied by other signs of tampering, such as unexpected topology changes (Rule 1) or MAC/IP inconsistencies (Rule 3).

Rule 3: ARP and MAC Spoofing Detection

The third rule addresses spoofing attacks, where a malicious device may impersonate legitimate hosts by forging MAC or IP addresses. This layer is critical for identifying stealthy rogue devices that are connected behind rogue switches to perform man-in-the-middle (MITM) attacks. Such devices often bypass port-based controls or baseline MAC mapping checks established in Rule 2 by mimicking legitimate network behavior.

To detect these threats, the framework periodically retrieves ARP cache data from multiple legitimate hosts distributed across different access switches (e.g., h1 on s2, h5 on s3, h9 on s4, and h13 on s5). While this multi-host perspective ensures broader visibility within the wired LAN, primary preference is given to h1, as it actively performs network scans and communicates with other devices more frequently. As a result, its ARP cache is typically updated faster, making it the most reliable source for identifying MAC–IP inconsistencies and detecting spoofing behavior in real time.

The script scans for the following anomalies every 10 seconds:

- **MAC Spoofing**: The same MAC address appears under multiple IP addresses.
- **ARP Spoofing**: A single IP address mapping to multiple MAC addresses.

These patterns are direct, vendor-neutral signs of identity impersonation that a trusted host can check quickly. They stay reliable in DHCP environments because we match on the MAC first, so normal IP changes don’t create noise while real spoofing still shows up. They also reflect how attackers or a rogue downstream switch can manipulate the network through ARP poisoning or MAC cloning to corrupt ARP caches and switch CAM tables,

redirect traffic, hide additional devices, and bypass port-level controls and device-registration policy, which is exactly what our correlation and alerting are built to catch in real time.

Alerts from this rule are treated as high priority, especially when correlated with topology or device mapping anomalies from Rules 1 and 2. The scanning interval may be adjusted based on the network environment, particularly in cases where IP assignment changes occur frequently due to device reconnections.

5.3 Insertion of Rogue Switch and Device

To simulate a real-world network compromise, a rogue Open vSwitch (OVS) switch was introduced into the running Mininet topology after the legitimate setup was fully stabilised. This rogue switch was externally connected to the access switch s3, imitating a physical insertion into a live LAN through an unused network port.

A rogue device was also introduced and linked to the rogue switch using a virtual Ethernet connection. This setup replicates an attacker connecting an unauthorised switch along with one or more hidden devices in order to blend into the network without being immediately detected.

The insertion was performed from outside the Mininet environment to reflect a realistic scenario where an attacker interacts with the underlying system directly, without Mininet's awareness. This method allows the detection framework to validate whether it can identify unauthorised topology changes and hidden device activity introduced through unmanaged connections.

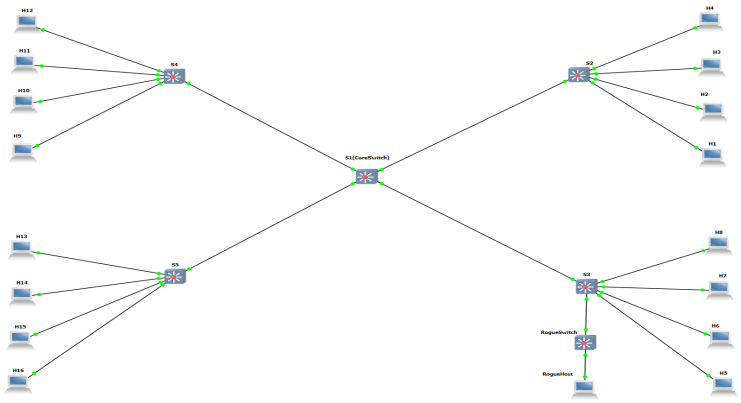

Figure 3: Topology after adding Rogue switch and device

5.4 Detection Based on Topology Changes

Once the framework is deployed, the topology monitoring script runs in the background and periodically checks for any new ports. When an unauthorized change, such as a rogue switch connection, is detected, the system immediately raises an alert. The screenshots below capture a real detection scenario where a new unauthorised port was identified.

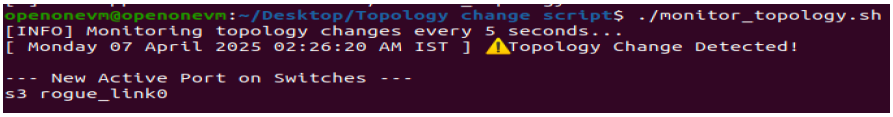

Figure 4: Real-Time Topology Change Detection Triggered

The script logs the moment a new port (rogue_link0) became active on switch s3, indicating a possible unauthorized link.

Figure 5: Email Alert Sent Upon Detection

An automated email alert was immediately triggered via SMTP, notifying the administrator of the detected rogue switch connection. The alert includes the exact timestamp and the specific switch-port details where the anomaly was observed, enabling precise identification and investigation.

5.5 Detection Rule Based on Unregistered Devices

Additionally, the second detection rule was running alongside the topology monitoring script. It prioritises MAC address verification. If a new, unregistered MAC address is detected, it is immediately flagged as rogue, regardless of its IP address. This approach is particularly important in DHCP-based networks, where IP addresses may change frequently but MAC addresses remain stable and unique identifiers.

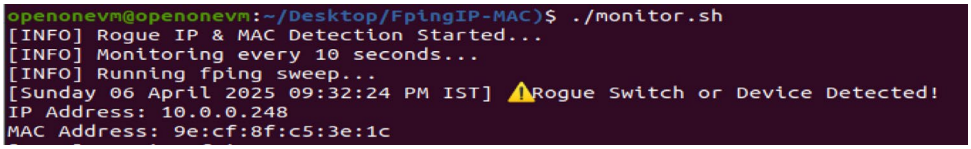

Figure 6: Rogue Device Detected via MAC Mapping

This screenshot shows the terminal output from the MAC detection script. A device with MAC address 9e:cf:8f:c5:3e:1c was identified at IP 10.0.0.248. Since this MAC was not listed in the baseline, it was flagged as a rogue device.

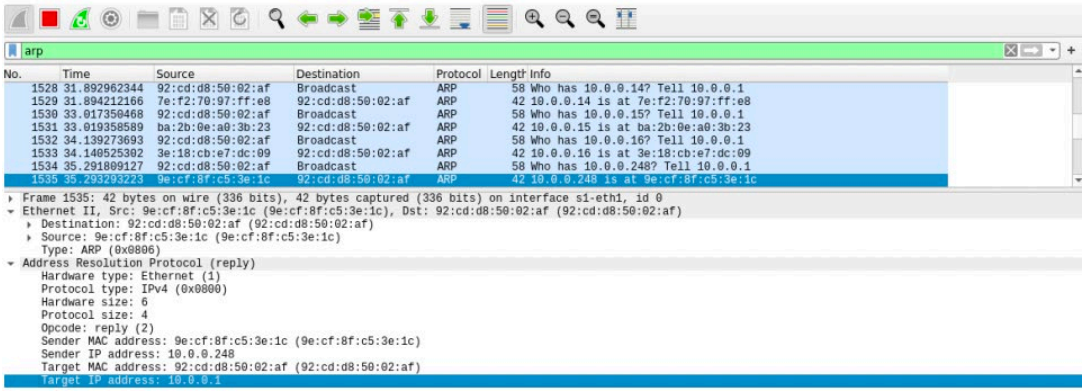

Figure 7: Wireshark Traffic Captured Near H1 host

This ARP reply packet confirms the MAC–IP mapping observed by h1 during baseline or live scan verification. In this frame, IP address 10.0.0.248 is associated with MAC address 9e:cf:8f:c5:3e:1c. Such entries are collected and compared against the trusted MAC–IP baseline in Rule 2 to identify unregistered or unauthorised devices. Any deviation from expected mappings triggers an alert, helping enforce device-level integrity within the LAN.

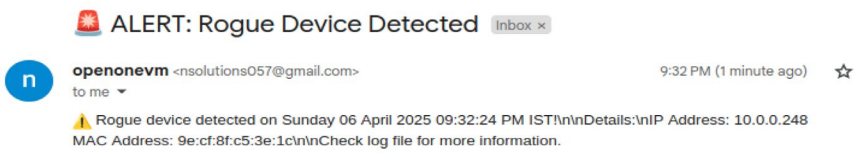

Figure 8: Email Alert for Topology Change

An automated email alert was immediately triggered via SMTP, notifying the administrator of the detected rogue switch connection. The alert includes the exact timestamp and identifies the affected port (rogue_link0) on switch s3 as observed by Rule 1. Additionally, Rule 2 raised a high-priority alert due to the appearance of an unregistered MAC address, further confirming the presence of a rogue device introduced via the rogue switch.

5.6 Detection Rule Based on MAC and ARP Spoofing

While topology changes and unregistered devices can expose many rogue setups, a determined attacker may still evade detection by impersonating known devices. This rule adds a critical layer of protocol-level inspection to uncover such spoofing behaviour.

5.6.1 MAC spoofing detection

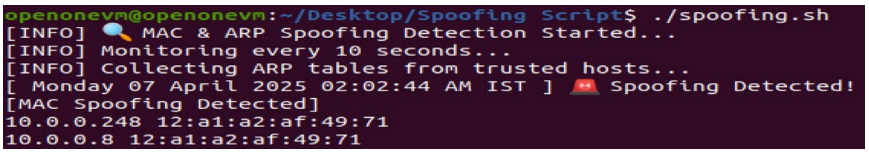

Figure 9: Spoofing Detection Triggered via MAC Conflict

In this scenario, a rogue device connected behind a rogue switch spoofed the MAC address of an already registered device. The detection script identified that the same MAC address (12:a1:a2:af:49:71) was simultaneously associated with two different IP addresses (10.0.0.248 and 10.0.0.8). Since this MAC was part of the trusted baseline, Rule 2 did not flag the device. However, Rule 3 successfully identified this as a MAC spoofing incident, which is an impersonation pattern commonly introduced by rogue switches to stay hidden. Given that these attack patterns are relatively common at Layer 2, there remains some scope for downstream evasion, which our Rule 3 is designed to mitigate.

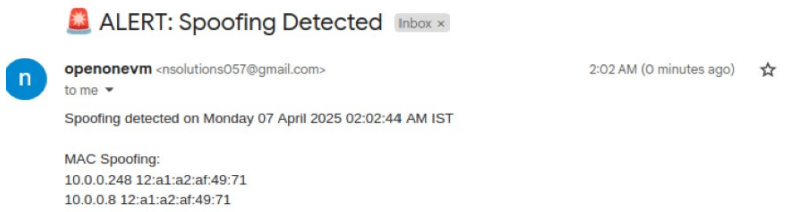

Figure 10: Email Alert Notifying Mac Spoofing Detection

An SMTP-based email alert was generated automatically, detailing the spoofed MAC address, the conflicting IPs, and the timestamp. This confirms that MAC spoofing can bypass earlier rules but still be caught by protocol-level analysis.

5.6.2 ARP spoofing detection

Although the device registration process in Rule 2 relies on MAC address verification, there still exists a narrow window for ARP spoofing, particularly when a rogue device impersonates a legitimate IP address with a different MAC. These cases are rare due to strict MAC filtering in Rule 2, but they can still occur when attackers reuse known IPs to bypass registration logic.

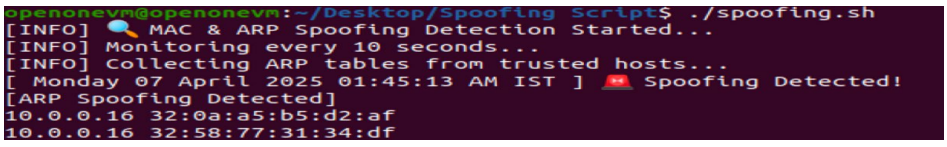

Figure 11: ARP Spoofing Detection Triggered

In this example, the spoofing script detected that the same IP address 10.0.0.16 was being claimed by two different MAC addresses: 32:0a:a5:b5:d2:af and 32:58:77:31:34:df. This is a typical indicator of an ARP spoofing attack, where the rogue host attempts to intercept traffic intended for a legitimate device.

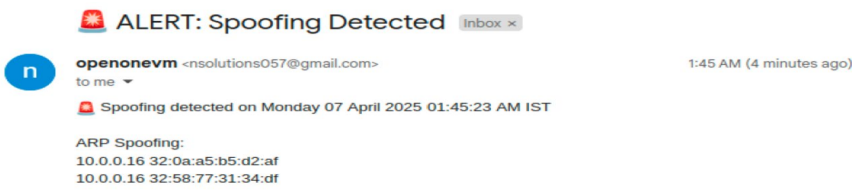

Figure 12: Email Alert Notifying ARP Spoofing Detection

An immediate alert was generated and sent to the administrator, showing the conflicting MAC addresses for the same IP. This helps in detecting impersonation attempts even when attackers try to reuse legitimate IPs.

5.7 Alert Prioritisation Logic

In dynamic environments, where legitimate devices may occasionally be moved or reconnected, a single topology change detected by Rule 1 is assigned medium priority by default. However, if that change is immediately followed by a MAC address mismatch (Rule 2) or an IP to MAC inconsistency (Rule 3), the alert level is escalated to high. When all three rules are triggered within the same observation window, the framework flags the event as critical, as it strongly suggests that a rogue switch is being used to connect multiple devices using a single legitimate switch port, indicating a highly suspicious or malicious activity. This layered prioritisation helps reduce false positives while ensuring timely and appropriate responses to compound threats.

6. Conclusion

This paper introduces a lightweight, real-time framework for detecting rogue switches in wired Local Area Networks by correlating topology monitoring, MAC address validation, and protocol-level spoofing analysis. The approach enables reliable identification of unauthorised switch insertions and downstream rogue devices through independent yet complementary detection rules, ensuring timely validation of network integrity. Targeted at small and medium-sized enterprises, the framework is vendor-neutral, cost-effective, and deployable without specialised hardware. Experimental evaluation confirms effective detection of topology anomalies, MAC spoofing, and ARP-based attacks, with automated email alerts supporting rapid administrative response. Future work will focus on visual topology dashboards, SIEM integration, and enhanced cross-rule correlation to further reduce false positives and strengthen post-admission network visibility.

Abstract: This paper presents a follow-up study to earlier research on cryptocurrency crime, again drawing on the case of an elderly woman defrauded by an online platform known as RSI-Platform. Whereas the initial study focused mainly on on-chain analysis within the blockchain environment, the present work shifts attention to off-chain approaches, applying open-source intelligence (OSINT) techniques to deepen investigations into crypto-related fraud. By systematically examining diverse input data—such as names, phone numbers, email addresses, and URLs—this study conducts link analysis and aims to build detailed profiles of potential suspects, thereby advancing understanding of the strategies and methods used in cryptocurrency scams. The analysis aims not only to trace the scammers' digital footprints but also to reveal networks and connections to other fraudulent platforms that support these activities. Moreover, this research seeks to raise public awareness about the scale and operation of fake online investment schemes in the crypto sector. By exposing the vulnerabilities exploited by offenders and illustrating how OSINT can be used to detect and disrupt such scams, the paper adds to ongoing discussions on cybersecurity and consumer protection in the fast-changing field of digital finance. Additionally, the findings are intended to offer practical insights for law enforcement agencies, policymakers, and the wider public, encouraging a more informed and proactive response to the threats posed by crypto-related fraud.

Keywords: Cybercrime, Cybercrime investigations, Cryptocurrency scams, Fake investments, OSINT

1. Introduction

Botha et al. (Botha, Singh, & Leenen, 2026) examined a fraudulent cryptocurrency investment and trading scheme by applying an investigative process introduced in earlier work (Botha, Singh, & Leenen, 2025). The previous study focused more heavily on on-chain analysis conducted directly on the blockchain, while giving relatively less consideration to off-chain analysis. The on-chain analysis was conducted using the tool Breadcrumbs, a cryptocurrency investigation tool that offers a transaction tracing platform for digital assets.

In contrast, this investigation study concentrates mainly on the off-chain analysis, which incorporates a range of OSINT methods and techniques. OSINT involves gathering, processing, and correlating information that is publicly accessible from open data sources like social media, forums, blogs, public government data, publications, or commercial data. OSINT methodologies begin with initial input data and employ advanced collection and analysis techniques to progressively enhance understanding about a target individual or organisation. As each new piece of information is discovered, analysts move closer to their ultimate objective (Pastor-Galindo, Nespoli, Gómez Mármol, & Martínez Pérez, 2020). Two types of OSINT exist, passive and active. Passive OSINT is the process of gathering information from publicly available sources, as described above, and similar open data repositories (Kolenbrander, 2025). In the case of an investigation, passive OSINT analysis aims to collect personal data about a target without any direct interaction with them. This method utilises various tools to find specific details, aimed at constructing a profile of the target individual (Botha, Singh, & Leenen, 2025). Active OSINT typically involves the use of a program or script to collect data and leaves a log behind (Kolenbrander, 2025). Active OSINT analysis also entails interacting with a target person under deceptive circumstances, such as using a fake or undercover profile, to persuade them into disclosing personal information. This approach, however, carries a higher likelihood of the target discovering the tactic used by the investigator, potentially resulting in them changing their behaviour. This also raises legal and ethical issues, including the risk of violating the policies of legitimate platforms (such as social media) and concerns about possible entrapment. What strategies are allowed can differ significantly between jurisdictions. For this investigation, no active OSINT methods were utilised. Active OSINT can also considered hacking. For example, if it is possible to manipulate a messaging application's metadata to expose the IP of the other party on the chat, it is considered hacking (Berkman, 2026; Hwang, Lee, Kim, Lee, & Kim, 2022; Hwang, Lee, Kim, Lee, & Kim, 2022).

This paper discusses the strategies and tools employed in this study, the theories investigated and the ultimate conclusions reached based on facts and evidence found. The authors first outline the case study's background

and context, followed by an off-chain analysis of the incident. The off-chain analysis employs several OSINT techniques and methods. After sufficient intelligence has been collected to profile the target entity, a link analysis is performed. The final stage addresses the associated law enforcement procedures. The expanded OSINT sections are intended to serve as a proposal for refining the process suggested in (Botha, Singh, & Leenen, 2026). The final section concludes the paper's main findings.

2. Case Background

The previous study proposed a theory that the ex-son-in-law (referred to as 'Mr-X' in this paper) could have been collaborating with the scammers. Note that investigators tend to use the term theory and not hypothesis in their investigations. For this paper the term "theory" will be used and refers to a "working theory" or "hypothesis". It is quite common for fraudsters to use local individuals to attract potential victims. These intermediaries are typically given some type of compensation for identifying and attracting victims. The particular scam platform under examination is called RSI-Platform and was ran out of the website 'https://rsi-platform.io' (note that the web domain is not active anymore since the scammers must have taken it down). The victim, an elderly woman, was persuaded to invest in the platform, which was portrayed to be a global online trading entity based in the United Kingdom (UK), integrating traditional investments with crypto-based funding and trading mechanisms. More details on the background can be found in the previous study, (Botha, Singh, & Leenen, 2026).

This study pursues two primary objectives:

- Collect online, off-chain information to attempt to identify the suspect, and
- To investigate and substantiate the hypothesis that 'Mr-X' is involved with the scammers.

The first author of this paper contacted TCG Forensics (TCG Forensics, 2026) and Breadcrumbs (Breadcrumbs, 2023) for support with the OSINT techniques, and both companies agreed to help. Craig Pederson, the CEO of TCG Forensics, contributed by attempting to identify the scammer and by gathering as much online information as possible. Abraham Berkman, Head of Intelligence at Breadcrumbs and the second author of this paper, also assisted by collecting data to determine the scammer's identity and to either confirm or dismiss the hypothesis that Mr-X was involved with the scammers, or whether he was in fact a genuine victim. Both Pederson and Berkman have backgrounds in OSINT and cybercrime investigations.

The indicators point to the involvement of both offshore and local parties, which aligns with a syndicated operation. In these cases, funds are transferred directly into crypto-exchange accounts using a specific reference number that routes the funds to the actor's wallet. This process circumvents many fraud prevention measures and enables money laundering by avoiding traditional banking channels. Once the credit reflects in their crypto-exchange account, the actor is then able to transfer the funds onwards.

3. Investigation Process

Similarly to the previous study, this analysis also follows the investigative process proposed by (Botha, Singh, & Leenen, 2025). The process has five phases, namely:

1. Data collection
2. Analysis
3. Theory development and validation
4. Suspect identification and reasonable grounds
5. Legal action

3.1 Data Collection

This section provides an overview of the collected data (evidence) from the victim. This paper focuses exclusively on the off-chain data that was gathered. The victim provided the following inputs *(names and contact information are redacted)*:

- *Suspect website domain*
- www.rsi-platform.io
- Screenshots of the suspicious domain.
- *Cryptocurrency addresses linked to the suspect domain. The preliminary tracking of these crypto transactions is documented in the earlier study (Botha, Singh, & Leenen, 2026)*
- *Names*

- List of names linked to the suspect domain – contacts communicating via WhatsApp and phone calls (numerous persons and names, which are likely all aliases).
- *Phone Numbers*
- List of numbers in connection to the suspect domain from which calls to the victim were made (SA and UK numbers)
- *Email Addresses*
- s#####e@cryptodotcom.info
- List of scammer names@###-platform.io
- *Physical Address*
- # B### St, London E## #BG, UK

3.2 Analysis

The analysis employed three basic steps in iteration, based on advice from an OSINT expert from Hawk Eyes OSINT and Breadcrumbs (Hawk Eyes, 2026) (Berkman, 2026):

- **Evidence Overview**: An examination of the evidence at hand to gain an understanding of the case, identification of areas for evidence enrichment and development, and affirmation or refutation of theories.
- **Evidence Enrichment**: Based on the evidence at hand, various tools and investigation methods were employed to process and further enrich the evidence base. This can also be done from a completely objective outlook or an effort to affirm or refute a running theory.
- **Theory Development (see Section 2.3)**: Based on the evidence overview, theories regarding the case were developed and those theories had to be affirmed or refuted by further evidence enrichment.

Typically, a case starts with preliminary evidence supplied by a client or victim (see Data Collection in Section 3.1). This initial evidence must be analysed so that a working theory can be formed, or so that potential ways to enrich the evidence can be identified. When such opportunities are found, the evidence should be enriched and then re-examined until a theory is developed. All new information that appears to be connected to the suspect should be incorporated into a link analysis diagram, (see section 4, Figure 4). After a theory has been developed, additional evidence must be collected and repeatedly reviewed until the theory is either supported or disproved. If the theory is disproved, the investigator must reassess the evidence and formulate a new theory. This iterative process continues until a theory is confirmed and the case can be closed. See Figure 1, which illustrates this process.

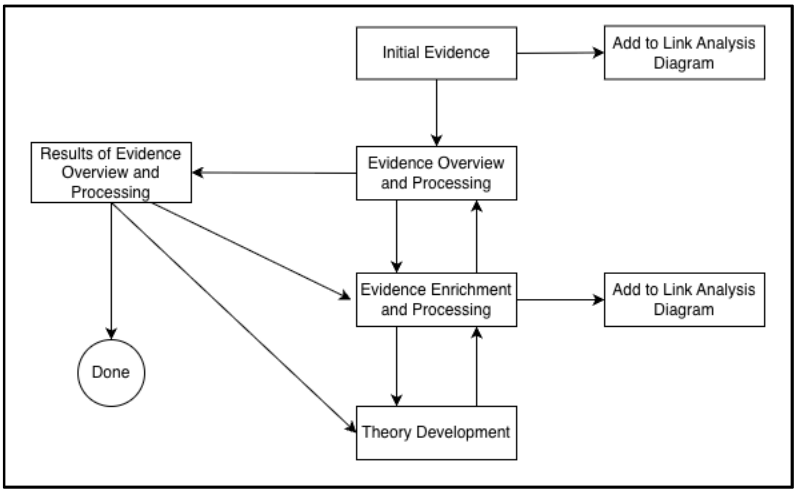

Figure 1: OSINT Investigation Process

In this segment of the analysis, OSINT methods are used to attempt to reveal the suspect's identity, based on the inputs and details provided by the victim. The proposed process by (Botha, Singh, & Leenen, 2025) does not give enough details on steps to be followed in the off-chain analysis, specifically with respect to the OSINT techniques. The steps seen in Figure 1 are added to the analysis phase in this investigation.

3.2.1 Evidence overview and processing

The client provided evidence as listed in Section 3.1. This section goes through all evidence and process them to gain more insights.

Domain Name

Because the scam originated from the website at the domain "https://rsi-platform.io", the initial step was to collect any further information associated with that domain. As the site is currently offline, the WayBackMachine (WaybackMachine, 2026) was used to retrieve historical data about its structure. The aim was to determine whether a comparable website run by the same offenders was still online, which would allow for network monitoring and a more detailed understanding of how the scam operated. Only a single screenshot from October 2022 was available on Wayback Machine (see Figure 2). This suggests that the site operated with limited capacity, received little traffic, and was active only for a short period. By using Chrome's 'inspect' tool, the screenshot revealed the site's HTML, CSS, and links to portions of its JavaScript. Distinctive code fragments were then extracted and searched on NerdyData (NerdyData, 2026) to identify other websites that might be using the same snippets. A further goal was to identify any extra information that might be obtained from the website's front end, such as additional phone numbers or email addresses. Ultimately, no further information could be collected.

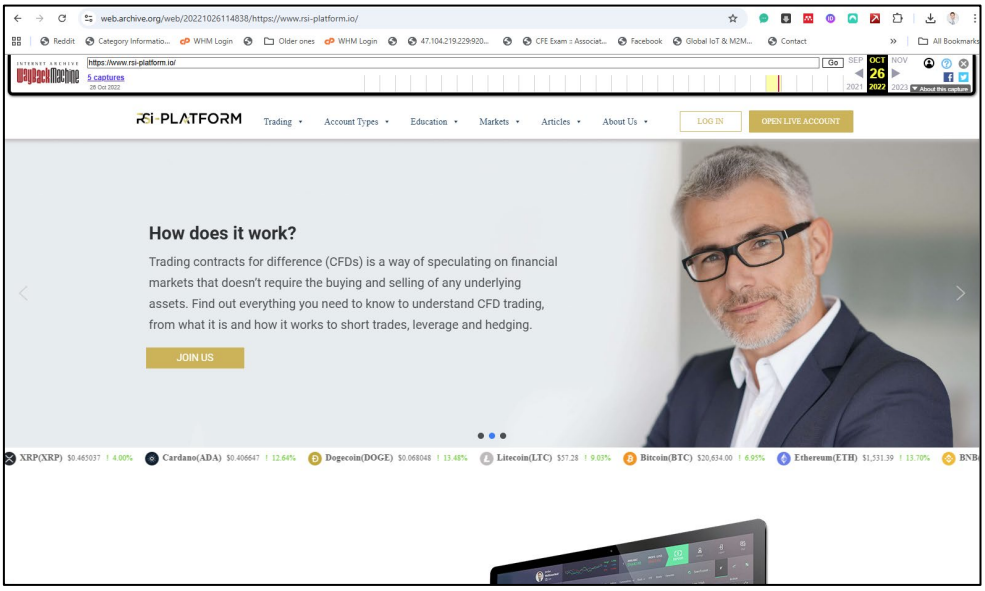

Figure 2: RSI-Platform - Home Page

WHOXY (WHOXY, 2026) reported that there is currently no active hosting on the domain. It does, however, provide information on the most recent registrar, as illustrated in Figure 3. Additional registrar data for the 2022 period may be obtainable directly from the registrar upon request. Particular focus should be given to the payment method used to acquire the domain in 2022.

MX Toolbox (MXToolbox, 2026) shows that there are currently no functioning mail routes, redirects, or traceable records linked to the domain. Opencorporates (opencorporates, 2026) further indicates that the supposed 'company' called 'vestpro', which the website claims is registered in the Seychelles, appears not to exist. There is no matching company registration or recognised legal entity connected to the site. Taken together, this strongly supports the conclusion that the rsi-platform.io website was precisely what it seems to be: just a small collection of pages created to lure in and reassure prospective victims. None of the claims or information displayed on the rsi-platform.io site can be verified against any reliable, factual sources.

The website scam detector (scam-detector.com, 2025) provides original information, reporting, reviews and analysis on websites, domains and e-commerce platforms, and advises if these are legitimately, safe and trustworthy. The www.rsi-platform.io web domain received a score of 40.7% from scam detector which signals risk and red flags. The domain was created on 23 June 2022, and the victim was scammed starting in December 2022. Shortly after the domain was created, scam detector also indicated it has a proximity to suspicious websites of 73% and a phishing score of 78%. The website's meta data was poorly configured which would not

help its online presence and resulted in a loss of credibility. The domain was active for 1 year, 11 months before it became inactive.

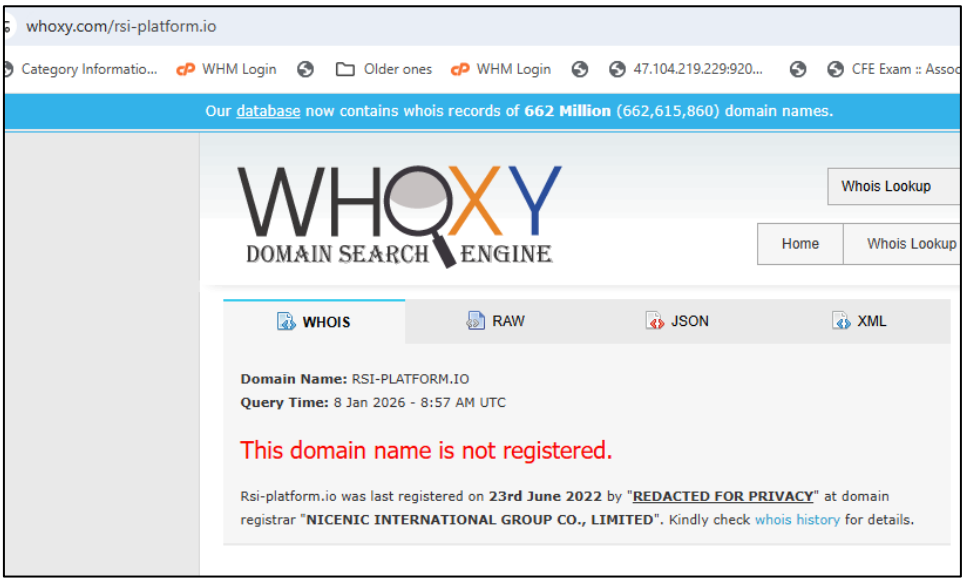

Figure 3: WHOXY Domain Search Engine

Another search result from Google pointed to the website www.55brokers.com, which suggests that RSI-platform appears to operate as a UK-based entity, with the authority to provide services in the UK. Nonetheless, its regulation is solely in St. Vincent and the Grenadines, classifying it as offshore. Therefore, this is typically indicative of a scam (55BROKERS, 2025).

Names and Contact Information

The victim provided a list that included names and phone numbers from South Africa (SA) and the UK. Through Truecaller (Truecaller, 2025), it was discovered that the SA numbers are linked to the RSI-platform ZA Office and that these numbers are Voice-over-IP (VoIP).

Regarding the list of email addresses all belonging to the domain RSI-platform.io, various user complaints were found on websites like ScamAdviser and Trustpilot (Trustpilot, 2023), involving unsolicited emails promoting 'guaranteed' investment opportunities or recovery services for lost funds. The platform has been reported as 'pig butchering' or advance-fee scams, where scammers build trust via email or chat, then request deposits or personal information. Pig butchering is an investment scam where fraudsters gain the trust of victims of time and then deceive them into investing in fake investment platforms (often fake cryptocurrency investment platforms) (DFPI, 2025).

No reliable business or professional profiles associated with any of these email names could be connected to the email addresses in recognised directories such as LinkedIn or official corporate registries.

3.2.2 Evidence Enrichment

Domain Name

A lookup of the domain in BigDomainData (BigDomainData, 2026) showed that it was registered via the Hong Kong–based registrar Nicenic International Group Co. by an individual named 'Tyron Cantrell' from 'Gwynedd County, Nigeria'. Gwynedd County is located in Wales, and no corresponding Gwynedd County could be identified in Nigeria. A review of the hosting provider, NiceNic, revealed that the platform operated without any KYC (Know your Customer) procedures and accepted payments through several methods, including cryptocurrency. This setup made it possible for clients to submit false registration details and pay in a pseudo-anonymous manner using cryptocurrency. Linking this information to the cryptocurrency addresses tied to the scammers could move the investigation forward, effectively bringing together OSINT and blockchain analysis. NiceNic's website also contained links to the platform's social media (SM) accounts on Facebook, X (formerly Twitter), and Pinterest. NiceNic cryptocurrency payment addresses included, but not limited to:

- 0xEd…61B8 - CircleCoin(USDC)

- 0x5E…2297 - USD_Tether (USDT)
- Bc1q…4mfa – Bitcoin (BTC)

By combining the on-chain and off-chain analysis, it also shows how Web2 (OSINT) and Web3 (on-chain or blockchain) investigations complement each other and are not mutually exclusive. In Web2, people depend on centralised services—such as social networks, online banking, and search engines. Web3 introduces a new model built on decentralised infrastructure and applications, such as the BTC blockchain (Lacity & Carmel, 2024). For example, in this case, discovering that the hosting company of the scammers domain accepts payment in crypto and discovering the payment addresses via OSINT, provided a new channel to trace via WEB3 (blockchain) (Berkman, 2026).

Names and Contact Information

Based on the findings from the domain investigation, it was evident that the perpetrators of the scam took deliberate steps to evade detection by using false information to conceal their identities. This conclusion was reinforced by the OSINT industry (OSINT Industries, 2026) reports, which showed multiple names associated with the same phone number, as well as the generic names given to the victims. As a result, attempting to investigate the names and contact details through traditional means would likely generate numerous false positives and consume valuable investigative time. The priority, therefore, shifted to identifying links between the contact information and other websites and/or members of the victims' families.

Using Maltego transforms, the transforms for Cyber Threat Intelligence (CTI), Corporate Intelligence, WhoisXML and Social Links were run on all the provided phone numbers and email addresses. Maltego is a cyber investigation and link analysis tool (Maltego, 2026). Additional searches were made on several of the phone numbers and email addresses using IntelTechniques (IntelTechniques, 2026), Breach Directory (Breach Directory, 2026), Non-Nonsense (NO-NONSENSE, 2026), FreeCarrierLookup (FreeCarrierLookup.com, 2026) with no results.

XDS (XDS, 2026) was used to conduct searches on telephone and/or mobile numbers. These searches returned the names, surnames and identity (ID) numbers linked to each queried number. Numbers identified as South African were subsequently verified against the CRDB Porting database (Porting, 2026) to establish the network provider for identification purposes and potential further investigation via a subpoena process. The numbers were confirmed as ported and still active on the networks of Vodacom, Telkom Mobile and SVSGNP (Saicom Voice Services).

Google searches were carried out on the names associated with the RSI platform that were supplied by the victim, and each of these names appeared in connection with negative reviews on hellopeter.com and Trustpilot. One positive review was identified on HelloPeter (hellopeter.com, 2025), but it is most likely a self-authored post made during the early phase of the scam. In the absence of a precise chronology of events, it cannot be conclusively established that this review is a self-review. Additional potentially relevant information might be available and could be obtained from HelloPeter through a subpoena. Should the review ultimately be classified as a self-review intended to bolster the scam's legitimacy, this would align with a common syndicated pattern. Although the names provided are not genuine names but rather aliases used to interact with victims, their full forms will not be disclosed in this paper. It can be noted, however, that the names are characteristic of white, English-speaking South African men and could just as plausibly be typical UK names.

WhatsApp chat logs between the victim and the suspects were recovered and imported into Maltego. However, these conversations did not reveal any additional information about the scammers' real identities beyond the aliases they used.

The provided email address, s######s@cryptodotcom.info, was subjected to various verification tools, revealing that the email account does not exist.

Mr-X

In addition, searches were made for the SM accounts of Mr-X. The searches focused on the subject's personal gmail address, the subsequent username and variations of the subject's name. A use of the service 'WhatsMyName' (WhatsMyName, 2026) revealed a Pinterest account, Roblox account and Facebook account using the target username. The Pinterest account contained a profile picture common amongst military men, this being consistent with the known military background of the subject. A reverse image search of the subject's Pinterest profile image revealed a YouTube account using the username and containing the exact same profile

image of the Pinterest account. A Google Dorks search, using the query 'person:(('name') 'surname') AND site:linkedin' while using a VPN set to SA (the home country of the target) revealed the target LinkedIn in profile.

3.3 Theory Development and Validation

Over the span of this investigation, three distinct theories were formulated and subsequently tested and validated.

3.3.1 Theory 1 – Mr-X is a victim

SA law enforcement reported that they suspect a group from the country of Georgia of being responsible for the scam that targeted the victims. It was initially believed that Mr-X had first fallen prey to the scam and, before realising it was fraudulent, had encouraged his wife and mother-in-law to use the platform, resulting in them being scammed as well. In this scenario, Mr-X would be considered a victim, along with the complainant.

By comparing the timeline of the WhatsApp conversations between the ex-husband and the RSI brokers with the victim's testimony, it was observed that a coherent pattern of interaction between Mr-X and RSI leading up to his recommendation that the victim invest in the platform. However, because the WhatsApp record is so extensive, the precise nature of these interactions remains unclear, making it difficult to draw firm conclusions.

3.3.2 Theory 2 – Mr-X worked with RSI-platform

Since it was Mr-X who introduced the victim to the platform and urged her to invest funds in it, the question arises as to what Mr-X knew about the platform's legitimacy at the time he involved his family. Moreover, the fact that Mr-X did not file a police report after it became clear that they had been defrauded supports the suspicion that Mr-X may have been part of the group operating the scam.

According to the victim's testimony, it was reported that Mr-X encouraged the victim to invest in the platform. After the scam was uncovered, Mr-X and his wife divorced, and Mr-X chose not to file a complaint with the Police. Furthermore, it was reported that efforts to obtain further information and evidence from Mr-X about the scam were met with reluctance. These circumstances led to the theory that Mr-X may have been complicit in the scam.

Because it was suspected that the target domain had been registered using cryptocurrency to pay the hosting provider, investigators initially attempted to identify links between the hosting provider's cryptocurrency payment addresses and the one used by Mr-X on VALR (ref to the initial study in (Botha, Singh, & Leenen, 2026)). This line of inquiry proved unproductive, however, as a closer review of the victim's testimony and the WhatsApp conversations strongly indicated that the RSI brokers themselves had access to their victims' VALR accounts. The victim repeatedly stated that she had deposited funds into her VALR account and then observed those funds reflected in her RSI account, despite not having initiated the transfer herself. She further testified that she had shared her VALR password with both the RSI brokers and her family. In addition, Mr-X stated in his chats with the RSI brokers that he had deposited money into his VALR account and was waiting for confirmation from them that the funds had appeared in his RSI account. This indicates that it was the brokers who transferred the funds from the VALR account to the RSI account. Given the brokers' level of access to Mr-X's VALR account, it is not possible to determine whether any outgoing funds were moved at Mr-X's instruction or even with his knowledge.

Mr-X's social media profiles were examined to identify any indications of communication or links between the Mr-X and the suspects, or with the domain hosting provider. This review covered Mr-X's YouTube content as well as his LinkedIn and Pinterest accounts. No clear associations were identified. Additional searches for any other online activity by Mr-X did not yield further information.

Refutation of the theory: A detailed review of the WhatsApp conversations between Mr-X and the RSI brokers revealed that Mr-X registered on and began investing through the platform in May 2022, and did not recommend it to the victim until August 2022.

3.3.3 Theory 3 – Mr-X hid money from his ex-wife

Evidence uncovered during the investigation indicates that Mr-X incurred debts to finance his investments in the suspect platform. One theory that emerged is that Mr-X was genuinely misled by the suspects.

Although it seems improbable that Mr-X was directly collaborating with the suspects, the fact that he failed to file a report with law enforcement remains suspicious. WhatsApp chat records indicate that Mr-X took out loans with high interest rates in order to finance his investment activities. Furthermore, when Mr-X started to incur

losses on the platform, he was instructed to deposit additional funds to keep his account balance up and avoid closing losing positions. It is very likely that Mr-X had built up a substantial level of debt before it became apparent that his money had been stolen. Since Mr-X and his wife divorced soon after the scam was uncovered, it is plausible that both the debt he accumulated and the naivety with which he lost his own and his family's money contributed to their decision to divorce.

There is also indication that a degree of financial mistrust existed between Mr-X and his wife. This inference is drawn from Mr-X's statements in the WhatsApp messages, where he expresses an intention to set up a separate trading account for his wife. This implies that, at that time, both he and his wife preserved a certain level of financial independence from one another.

Given the presumed extent of his financial autonomy and the monetary issues thought to be central to the couple's divorce, it is hypothesised that Mr-X had an incentive to conceal assets or liabilities from his wife in order to avoid weakening his position in the divorce settlement. Lodging a complaint with law enforcement would have opened his financial records to scrutiny, records that may otherwise have remained inaccessible to his ex-wife. This provides a plausible explanation for the target's refusal to cooperate with both law enforcement and private investigators, and it aligns with the available evidence in the case. As of the time of this revision, this remains the predominant working theory. Substantiating this theory would require a focused inquiry into Mr-X and his financial documentation. Such steps fell outside the remit of this investigation.

3.4 Suspect Identification and Reasonable Grounds

The first step in attempting to identify the suspects behind the scam was to analyse the names and phone numbers provided by the client. An examination of the evidence revealed multiple names connected to phone numbers. The phone number, +27-8##-6#6-### was shown as being connected to three names by an export file from OSINT Industries. This suggests that the suspects were using a text message one time code receiving service to open WhatsApp accounts and other necessary online presents. Any information found relating to this provided data would likely be fabricated and not lead to the guilty suspects.

The second attempt to identify the suspect was through the domain registration of the target domain, 'https://rsi-platform.io'. The discovered evidence showed that this too contained fabricated registration data. It was found, however, that the suspects likely paid for the domain registration with cryptocurrency This discovery led to a third strategy in identifying the suspects. By tracing the transactions from the suspects cryptocurrency addresses provided by the victim to a KYC compliant cryptocurrency exchange would allow law-enforcement to subpoena the exchange for the profile details behind the account. This strategy had already been carried out by law enforcement and they had successfully traced the transactions to the cryptocurrency exchange, Kyrrex, and sent a request for information. At the time of writing this paper, law enforcement had not received a response from Kyrrex. This remains the most likely route of gaining actionable information that could lead to the identity of the suspects.

3.5 Law Enforcement Function

This segment of the investigation is part of the legal action phase and is conducted by legal authorities to locate and prosecute the suspect, initiating the process of charging, arresting, imposing sanctions, recovering assets, and seizing funds. Refer to (Botha, Singh, & Leenen, 2025) for the detailed description of the entire process.

In this study, no legal measures were taken. It is advised that subpoenas be served on multiple mobile network operators, including Vodacom, MTN, and Telkom Mobile, to obtain IMEI information as well as any associated call and location records for the identified numbers. The subpoena should also reference any other SIM cards used in the same device(s) in order to build a complete picture of the activities. It is further recommended to subpoena the websites HelloPeter.com and Trustpilot in order to obtain the contact details of additional victims who filed complaints against the website rsi-platform.io and indicated that they were also defrauded by this scheme. Moreover, the contact information associated with the positive review, which appears to be a self-authored review by the perpetrators, may provide further data connected to the suspect.

Unfortunately, the scammers' identities are still unknown, and this stage cannot be fully carried out without adequate intelligence and supporting evidence. The perpetrators are highly skilled at concealing their tracks. The most viable approach is to trace the flow of funds on the blockchain and perform further on-chain analysis, in the hope that the scammers slip up and reveal information that can later be used in off-chain investigations. Every new detail uncovered and added to the link analysis brings us one step closer to identifying the scammers. The ultimate objective is to determine who they are and ensure they are brought to justice.

4. Link Analysis

Link analysis is the identification of relationships and connections between two entities such as individuals, organisations, etc. (Holzer, Dietz, & Yang, 2016). This technique visually represents interconnected entities as nodes and links, facilitating a clearer understanding of the data and its underlying structure (Cambridge Intelligence, 2025). The link analysis allowed for a visual representation of the relationships between the suspect and all other entities identified as being connected to them. These entities encompass all information provided by the victim, as well as any further links uncovered through the use of OSINT tools. The identified entities include mobile phone numbers, email addresses, physical addresses, names provided by the victim, names associated with mobile numbers as revealed by specific OSINT tools, mobile service providers, domain details, registrar information, and similar data points (refer to Figure 4). Although multiple linked entities could be discovered, the data is not enough to successfully identify a target suspect. When collecting information on a target, a case management strategy is needed to keep track and make sense of the findings. For this case, the link analysis and case management tool used was Maltego.

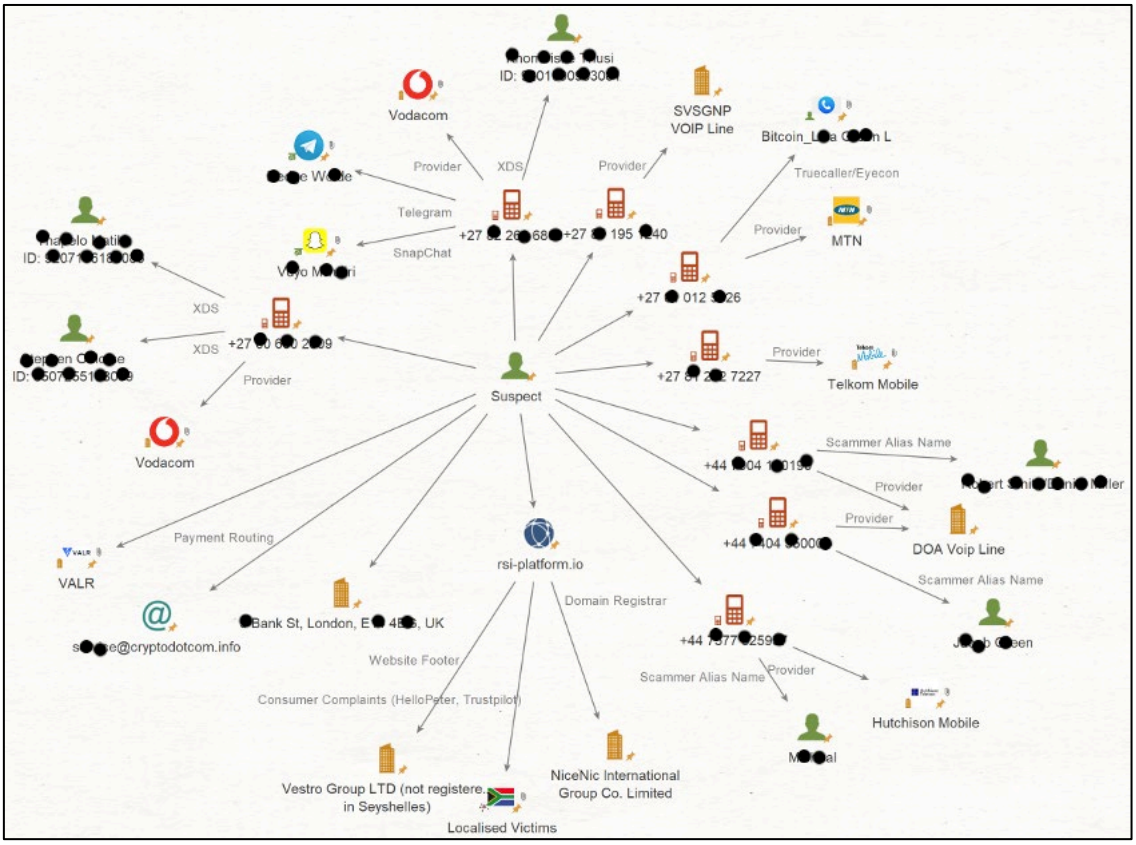

Figure 4: Link Analysis

5. Conclusion

This paper extends an earlier study that examined a particular instance of a fraudulent cryptocurrency investment scheme. While the previous work focused on on-chain (blockchain-based) analysis, the present study concentrates on off-chain investigation. It provides practical guidance by implementing a structured investigative framework previously proposed by the authors, aimed at law enforcement, regulators, investigators, analysts, and researchers. In this study, that framework is modestly refined by adding additional steps to the OSINT analytical phase and it illustrates the practical implementation steps. The author engaged two OSINT specialists to support the case analysis.

The first objective of the investigation was to identify the individuals behind the scam operated via the domain 'rsi-platform.io'. Both law enforcement and the client had already identified a promising route to uncovering the suspects—namely, the accounts they had opened on the Kyrrex cryptocurrency exchange. However, Kyrrex's lack of cooperation, combined with law enforcement's view that the offenders are likely outside SA's jurisdiction, underscores the challenges of maintaining law and order in a digital, transnational crime environment. When

victim and offender reside in different jurisdictions, and the amount stolen is too small to prompt action from international bodies yet large enough to financially devastate a household, victims are frequently left without any effective recourse.

The second objective was to validate the prevailing theory that the ex-son-in-law had been intentionally induced to incur an excessively large debt in order to trade on the RSI platform. Believing he was successful and hoping to increase overall profits, he then persuaded his wife and her family to invest as well. Once it became clear that the operators of the RSI platform were in fact criminals who had misappropriated their funds, serious domestic conflict arose, ultimately resulting in divorce. Seeking to conceal the magnitude of his debt and to improve his position in the divorce proceedings, the ex-son-in-law chose not to file a report with law enforcement in order to avoid disclosing his financial records.

As blockchain technology becomes more widely used, crimes and scams involving cryptocurrencies are also on the rise. Online fraud remains a serious global issue, largely because there is a lack of uniform, official regulation. Moreover, the borderless nature of cryptocurrency transactions has contributed to an increase in such scams within both financial and cybercrime domains. This paper also seeks to raise awareness of fake investment schemes and fraudulent cryptocurrency investment platforms.

Abstract: The rapid adoption of Internet Medical Things (IoMT) technologies in remote patient monitoring has reshaped healthcare delivery by enabling continuous, real-time clinical observation outside traditional care settings. However, this shift has also expanded the cyber-attack surface across heterogeneous, resource-constrained medical devices, wireless networks, cloud services, and third-party platforms. In cyber warfare, healthcare has become an incorporated target of geopolitics, with hospitals, remote monitoring systems, and emergency health systems being used to broaden the attack surface for adversaries to exploit. Existing security approaches for IoMT environments remain largely manual, fragmented, and reactive, limiting their effectiveness in dynamically assessing vulnerabilities and supporting timely defensive decision-making. In critical healthcare contexts, such limitations pose direct risks to patient safety, data integrity, and system availability. This research proposes a knowledge-driven methodology pipeline for semantic reasoning and partial automation to strengthen cyber defence in IoMT-enabled remote patient monitoring systems. The pipeline integrates domain ontologies, rule-based reasoning, and knowledge graph representation to formally model medical devices, vulnerabilities, attack vectors, potential cyber-physical impacts, and mitigation strategies. By structuring and linking heterogeneous security knowledge with external cyber threat intelligence, the proposed approach enables context-aware vulnerability detection, automated inference, and explainable security insights. The methodology follows a science and engineering research design, progressing from conceptual modelling to prototype development, semantic framework implementation, and validation. A vulnerability detection algorithm operationalizes the pipeline by systematically identifying exploitable weaknesses, assessing severity and impact, and recommending countermeasures through semantic queries and reasoning. Evaluation using representative remote patient monitoring scenarios demonstrates improved consistency, visibility, and timeliness in vulnerability identification compared to existing IoMT security frameworks. This work contributes to a practical, extensible, and automation-oriented semantic pipeline that enhances cyber resilience in healthcare systems considered part of the critical national infrastructure.

Keywords: Internet of medical things (IoMT), Healthcare cyber resilience, Vulnerability detection, Semantic cybersecurity framework, Cybersecurity governance

1. Introduction

With the evolution of IoT (Alsabah et al., 2025), WSNs (Ojha & Gupta, 2025) have become central to the development of real-time, data-driven healthcare solutions, supporting continuous patient monitoring, environmental sensing, and intelligent decision-making in modern smart healthcare systems. These technological advances have facilitated the creation of smart healthcare environments that support continuous monitoring, timely intervention, and improved quality of care, particularly for individuals living independently or managing chronic conditions (Alam Efat, 2025). Such environments are increasingly relied upon to provide safe and monitored living spaces in which health data can be collected, transmitted, and analysed by healthcare providers, allowing early detection of medical anomalies and timely clinical response.

Healthcare systems have increasingly become deliberate targets during armed conflict and geopolitical confrontation, transforming hospitals, emergency response networks, and remote patient monitoring (RPM) platforms into components of contested digital terrain. IoMT-enabled RPM systems extend clinical infrastructure into homes and community settings, creating a distributed attack surface that adversaries can exploit to degrade care continuity without physically striking hospitals. In this context, the proposed governance-aware semantic cyber defence framework offers strategic benefit by enabling early detection of vulnerabilities across interconnected medical devices, cloud services, and communication layers. By integrating knowledge graphs, rule-based reasoning, and regulatory control mapping, the framework enhances situational awareness not only at the technical level but also at the institutional governance level.

This is particularly important in wartime conditions where operational tempo increases, patch cycles are compressed, and device supply chains may be disrupted. A semantic model that links vulnerabilities to cyber-physical risk and compliance obligations enables healthcare providers to prioritize defensive actions in alignment with national resilience objectives. Rather than responding reactively to incidents, healthcare organizations can

proactively model cascading effects, such as compromised telemetry data influencing clinical decision-making. This reduces the probability that cyber interference escalates into clinical harm during periods of heightened geopolitical instability.

A specifically relevant adversary in this context is the hybrid actor. This type of actor is either a state-sponsored advanced persistent threat (APT) group or a ransomware organization operating with tacit state tolerance, seeking to generate coercive pressure without triggering overt military escalation (Deb, 2025). For example, during the Russia–Ukraine conflict, multiple cyber campaigns have targeted Ukrainian healthcare institutions and digital infrastructure, while ransomware groups such as Conti publicly aligned themselves with geopolitical objectives (Hansel & Silomon, 2024; Kapsokoli, 2025). In such scenarios, disruption of RPM networks could undermine chronic disease management, overload emergency departments, and erode civilian confidence in state capacity, thereby achieving strategic psychological and societal impact. A semantic, knowledge-driven defence architecture as proposed in this paper directly addresses this threat model by enabling traceable reasoning from exploited vulnerability to patient safety risk and governance escalation. By mapping device-level weaknesses to national cybersecurity frameworks and critical infrastructure oversight mechanisms, the framework strengthens healthcare cyber resilience against adversaries whose objectives extend beyond financial gain toward destabilization, coercion, or hybrid warfare. In a global environment where cyber operations increasingly accompany conventional conflict, embedding explainable, governance-aligned automation into IoMT ecosystems becomes not merely a technical improvement but a strategic necessity for protecting civilian populations and maintaining national stability (Ewoh & Vartiainen, 2024).

Within this context, the Internet of Medical Things (IoMT) has emerged as a critical enabling of connected healthcare. IoMT represents a specialized subset of the Internet of Things, integrating medical devices, sensors, actuators, and communication technologies to support patient monitoring, diagnosis, and treatment (SriPriyanka and Mahendran, 2021; Pritika, Shanmugam and Azam, 2023). These systems employ a wide range of devices, including wearable sensors, smart medical equipment, mobile applications, and cloud-based services, to enable continuous data exchange between patients, healthcare professionals, and service providers. Remote patient monitoring (RPM) systems allow patients to remain in their homes while clinicians receive real-time physiological data, supporting proactive and personalized care delivery (Bughio, 2023).

Despite these benefits, the increasing reliance on IoMT technologies introduces significant cybersecurity challenges. IoMT ecosystems are inherently heterogeneous, distributed, and resource-constrained, often lacking consistent security standards across devices, vendors, and deployment environments (Shah, 2026). Medical devices frequently rely on wireless communication technologies such as Bluetooth and Wi-Fi and transmit sensitive health data through cloud infrastructures, increasing exposure to cyber threats. Vulnerabilities within these systems can be exploited to compromise device functionality, manipulate medical data, violate patient privacy, or disrupt healthcare services, with potentially severe clinical consequences. Maintaining cyber resilience in IoMT-enabled healthcare systems is therefore a critical challenge. Traditional security approaches, which often rely on manual vulnerability assessment and isolated security controls, struggle to cope with the scale, complexity, and dynamic nature of IoMT environments. There is a growing need for structured, automated, and explainable security solutions capable of integrating heterogeneous security knowledge, identifying vulnerabilities in context, and supporting informed defensive decision-making (Bughio et al., 2024b; Ullah et al., 2025).

Beyond technical vulnerabilities, IoMT-enabled remote patient monitoring systems must be understood within the broader strategic context of critical healthcare infrastructure. As healthcare systems increasingly depend on interconnected medical devices and cloud-based services, cyber incidents no longer represent isolated technical failures but strategic risks affecting national resilience, public trust, and patient safety. Consequently, vulnerability detection mechanisms must support not only operational security teams but also governance, compliance, and policy-level decision-making. A knowledge-driven and explainable security framework enables strategic visibility across device ecosystems, supporting risk-informed resource allocation, regulatory compliance, and coordinated cyber defence at institutional and national levels. This research addresses this need by proposing a semantic framework designed to enhance the security posture of IoMT-based remote patient monitoring systems through partial automation, knowledge integration, and reasoning. By leveraging semantic technologies, rule-based reasoning, and knowledge graphs, the framework aims to support systematic vulnerability detection, impact assessment, and mitigation planning within healthcare environments considered part of critical national infrastructure.

This paper extends our prior work on conceptual modelling, ontology development, and preliminary semantic framework design (Bughio et al., 2024a; 2024b; 2024c) by introducing a governance-aware semantic cyber defence framework for IoMT-enabled remote patient monitoring systems. Unlike existing approaches that primarily focus on technical vulnerability detection, this research integrates cybersecurity analysis with institutional governance and regulatory compliance. The main contributions of this paper are as follows:

- A governance-aware vulnerability detection algorithm that formalizes the relationship between vulnerabilities, potential attacks, adverse cyber-physical impacts, and mitigation strategies, while incorporating risk classification and regulatory control mapping.
- An enhanced semantic framework that embeds governance-aware reasoning within an ontology-driven architecture, enabling automated, explainable, and context-aware vulnerability analysis.
- Integration of regulatory compliance and risk categorisation into the vulnerability detection lifecycle, providing traceability between technical security events and frameworks such as NIST Cybersecurity Framework and ISO/IEC 27001.
- A knowledge graph-based implementation that supports semantic querying, reasoning, and visualization of IoMT security insights for both technical and strategic decision-making.

By bridging semantic automation with cybersecurity governance, this work advances IoMT security from isolated technical detection toward a structured, explainable, and policy-aligned cyber defence capability.

2. Research Methodology and Design

In the field of computer science, researchers employ various methods to conduct their experiments. Broadly, these methods fall into two main categories: the scientific method and the mathematical method (Basili, 1993; Kelly, 2008). The scientific method, often regarded as the optimal paradigm for understanding software processes, products, people, and environments, involves observing the world, proposing models, measuring, analysing, and validating these models. It is subdivided into two approaches: the empirical method and the engineering method. This research adopts the scientific approach, specifically focusing on the engineering method subcategory. Research grounded in science and engineering enables researchers to validate theoretical predictions (Kelly, 2008). In this regard, researchers often propose solutions to problems by developing, measuring, and analysing techniques, methodologies, models, algorithms, or frameworks against existing solutions. In the engineering domain, the fundamental goal of 'creating functional solutions' is realized through three distinct levels, as identified by: *the conceptual level, the perceptual level, and the practical level*. Each of these levels is further elaborated as:

a) **Conceptual Level:** At this initial stage, innovative ideas are formulated, leading to the creation of new concepts. This process involves a detailed analysis of the problem at hand.
b) **Perceptual Level:** This level involves the development of new techniques based on novel approaches. It encompasses the design and development of specific tools, environments, or appropriate systems through implementation.
c) **Practical Level:** At this final stage, the focus shifts to the application of testing and validation techniques. Experimentation is conducted based on real-world scenarios, employing either laboratory or testing methods are used.

This research focuses on developing a semantic framework designed to facilitate partial automation and enhance the security posture of IoT networks used in remote patient monitoring systems. At the core of this framework is a domain ontology that encapsulates the semantics of the concepts and properties critical to the main security aspects of IoT medical devices utilized in such systems. This ontology is augmented with a comprehensive ruleset, complex queries, and mechanisms that enable automated reasoning over aggregated knowledge. Consequently, to address the various tasks required to develop a solution, the science and engineering research methodology has been adopted as the primary research method. *Figure 1.* shows the research pipeline based on the Science and Engineering research methodology for this research work.

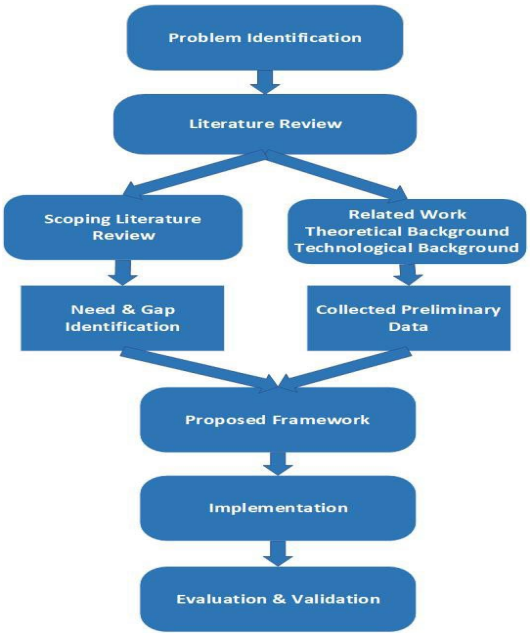

Figure 1: The Science and Engineering Methodology for Semantic Framework Development

2.1 Research Phases

This research is structured into two main phases, employing scientific and engineering methodologies. The first phase, problem formulation, clearly outlines the definition and origin of the problem. The second phase, proposing a solution, describes in detail the workflow of activities designed to resolve the problem.

2.1.1 Problem formalization

The research began with the identification of research problems, followed by a literature review (Bughio et al., 2024b) to explore the different techniques employed to tackle these issues. Based on the existing literature concerning modelling, processing and visualization challenges and verification and validation of IoMT security, the problem is formalized and presented in an algorithmic manner. This algorithm is designed to validate a use case and systematically detect vulnerabilities in Medical IoT devices, identify potential attacks that could exploit these vulnerabilities, assess possible adverse side effects arising from such attacks, and determine appropriate countermeasures to mitigate associated risks. In addition, the algorithm incorporates a governance-mapping layer that classifies detected vulnerabilities into operational, safety, and privacy risk categories, maps them to relevant regulatory controls (e.g., NIST Cybersecurity Framework and ISO/IEC 27001), and generates ontology-based compliance traceability links. This integrated approach ensures that vulnerability detection not only supports technical remediation but also aligns with institutional cybersecurity governance and regulatory requirements.

Use Case: If a patient is using a medical device, such as a defibrillator or a blood pressure monitor, which connects to services through network technologies like Wi-Fi or cloud-based systems, there is an inherent risk of vulnerability. These vulnerabilities could potentially be exploited by cyber attackers to compromise device functionality or patient data privacy. This not only jeopardizes patient health but also undermines trust in healthcare technologies. To safeguard both the patient and the device from adverse outcomes, it is crucial to implement robust countermeasures that effectively mitigate these vulnerabilities.

Algorithm 1 *Governance-Aware Vulnerability Detection in Medical IoT Devices*

Input: Person *P*, Medical Device *MD*, Service *S.*

Output: Vulnerabilities *V*, Attacks *A*, Adverse Side Effects *ASE*, Countermeasures *C*, Risk Categories *RC*, Regulatory Controls *REG*, Compliance Traceability *CT.*

Initialize:

$V \leftarrow \emptyset$

$A \leftarrow \emptyset$

ASE ← Ø

C ← Ø

RC ← Ø

REG ← Ø

CT ← Ø

Step 1: *Vulnerability Identification*

For each component in Medical Device MD:

Detect vulnerabilities

If vulnerability v is identified:

Add v to V

Step 2: *Governance-Aware Risk Classification and Compliance Mapping*

For each vulnerability v in V:

rc ← ClassifyRiskCategory(v) // Operational, Safety, Privacy

reg ← MapToRegulatoryControl(v) // NIST, ISO/IEC 27001, etc.

ct ← GenerateComplianceTrace(v, rc, reg)

Add rc to RC

Add reg to REG

Add ct to CT

Step 3: *Attack Identification*

For each vulnerability v in V:

Identify potential attacks exploiting v

Add identified attacks to A

Step 4: *Adverse Impact Assessment*

For each attack a in A:

ase ← AssessAdverseSideEffects(a)

Add ase to ASE

Step 5: *Countermeasure Selection*

For each vulnerability v in V:

c ← SelectCountermeasures(v)

Add c to C

Return:

V, A, ASE, C, RC, REG, CT

The structure of *Algorithm 1* directly reflects the gaps identified in the literature and aligns each processing stage with specific security requirements. The vulnerability identification stage captures device-level weaknesses as the foundational input for subsequent analysis. This is followed by attack identification, which addresses a key limitation in existing approaches that often treat vulnerabilities in isolation without explicitly linking them to

potential exploit scenarios. The adverse impact assessment stage extends traditional cybersecurity analysis by incorporating cyber-physical consequences, which is particularly critical in healthcare environments where attacks may directly affect patient safety. Subsequently, the countermeasure selection stage provides actionable mitigation strategies, supporting practical implementation of security controls.

The governance-aware layer, introduced in Step 2, represents the core contribution and primary novelty of this research. This layer integrates structured risk categorization into operational, safety, and privacy domains, maps identified vulnerabilities to relevant regulatory controls and generates ontology-based compliance traceability. Through this integration, vulnerability detection is elevated beyond purely technical remediation to also support compliance reporting, audit readiness, and strategic cyber risk management.

Algorithm 1 is not intended as a standalone procedure; rather, it is embedded within the proposed semantic framework. Each stage of the algorithm is operationalized through ontology concepts and relationships defined in RDF/OWL, rule-based reasoning mechanisms, and knowledge graph queries over integrated cyber threat intelligence data. This tight integration enables automated, explainable, and scalable vulnerability analysis across complex IoMT environments, supporting both operational security functions and higher-level governance objectives.

2.1.2 Proposed solution

In this research, the primary aim is to develop a governance-aware semantic framework to enhance the security posture of IoT networks used in remote patient monitoring (RPM) systems through partial automation, knowledge integration, and explainable reasoning. The framework leverages domain ontologies, rule-based inference, and knowledge graph technologies to systematically detect vulnerabilities, analyse their impact, and support mitigation planning.

At its core, the framework integrates heterogeneous security knowledge, including device characteristics, vulnerabilities, cyber threat intelligence, and regulatory requirements. Through semantic modelling and reasoning, the framework enables the identification of both known and emerging vulnerabilities, assesses their severity and potential impact, and recommends appropriate countermeasures.

A key distinction of this work is the integration of governance-aware reasoning, where detected vulnerabilities are not only analysed technically but also mapped to risk categories and regulatory controls. This enables traceability between operational security events and institutional compliance requirements, supporting both technical and strategic decision-making.

The solution methodology is structured into four phases, as summarized in Table 1. These phases follow a science and engineering approach, progressing from conceptual design to implementation and validation.

2.1.3 Phase I- conceptual model

In the field of software engineering, conceptualization plays a crucial role. This involves defining principles and design criteria essential for developing the domain ontology. Conceptualization organizes domain knowledge (background knowledge) into a conceptual model that articulates the problem and its solution using domain-specific vocabulary. Such structuring of information simplifies the understanding and communication of complex concepts within the domain.

This model establishes connections between concepts through various properties (relationships) that serve diverse purposes within the Internet of Medical Things (IoMT) context, addressing different scenarios and use cases. It offers a centralized repository and tools that enable effective sharing and communication among all system participants. This not only accelerates the development process but also enhances interoperability and the correlation of test results. This phase has been developed and validated in our previous work (Bughio et al., 2024a) and is reused in this study as the foundational layer for subsequent semantic modelling and reasoning.

Table 1: Solution Methodology Phases

Solution Methodology Phases		
Phase	***Title***	***Description***
Phase I	Conceptual Model	To define key concepts, relationships, individuals, and axioms for the conceptual model
Phase II	Prototype Development	Use semantic web technologies (OWL, RDF, and XML), de facto standards to verify the conceptual model by developing a prototype
Phase III	Governance-Aware Semantic Framework	To implement the semantic model and store CTI information in a knowledge graph
Phase IV	Evaluation and Validation	Evaluation and validation based on use cases and existing framework

2.1.4 Phase II- prototype development

In this phase, a prototype is developed to demonstrate the detailed workings of the proposed conceptual model. It is specifically designed to model and reason about anomalies and vulnerabilities within the IoMT system. The well-defined formalism RDF is utilized to create a domain ontology, capturing the semantics of the domain in terms of concepts and relationships. This includes defining instances of medical devices, vulnerabilities, and IoT networks. Semantic annotation is performed to enrich the domain ontology within the defined setting. This phase builds upon earlier work (Bughio, 2023) and is extended in this study to support integration with governance-aware reasoning mechanisms.

2.1.5 Phase III- governance-aware semantic framework

This phase represents the core contribution of this research. The proposed semantic framework extends prior work by integrating:

- the governance-aware vulnerability detection algorithm (*Section 2.1.1*),
- regulatory control mapping (e.g., NIST CSF, ISO/IEC 27001), and
- ontology-based compliance traceability.

The framework constructs a semantic model enriched with cyber threat intelligence, including data from the National Vulnerability Database (NVD) via API integration. Rule-based reasoning is applied over the knowledge graph to identify vulnerabilities, infer attack scenarios, assess impacts, and recommend mitigation strategies.

Unlike prior work (Bughio et al., 2024c), which introduced initial semantic modelling, this phase introduces governance-aware reasoning as a novel extension, enabling the alignment of technical vulnerability detection with cybersecurity governance and compliance requirements. This transforms the framework from a technical analysis tool into a decision-support system for both operational and strategic cybersecurity management.

2.1.6 Evaluation and validation

Evaluation and validation are critical for ensuring the reliability and applicability of the proposed framework. The evaluation assesses the effectiveness of vulnerability detection, reasoning accuracy, and governance mapping, while validation confirms alignment with real-world requirements and standards.

In this study, evaluation is conducted across multiple phases. The conceptual model has been evaluated in prior work (Bughio et al., 2024a, 2024c) . The prototype implementation has been validated in (Bughio, 2023). The governance-aware semantic framework is evaluated using representative IoMT use cases and knowledge engineering methodologies. These evaluation approaches assess the correctness of reasoning processes, the effectiveness of rule execution, and the overall performance of the framework in identifying vulnerabilities and supporting decision-making.

2.2 Strategic and Governance Implications

2.2.1 IoMT as Critical Healthcare Infrastructure

Healthcare systems are increasingly recognised as part of critical national infrastructure due to their essential role in maintaining public health and societal stability. The digital transformation of healthcare, particularly through IoMT-enabled remote patient monitoring, has introduced unprecedented connectivity and operational efficiency. However, this transformation simultaneously amplifies systemic cyber risk. As noted by the World Health Organization (World Health Organization (WHO), 2021) in its Global Strategy on Digital Health, the expansion of digital health technologies necessitates robust cybersecurity governance to ensure resilience and patient safety.

Cyber incidents in IoMT environments may lead not only to data breaches but also to direct cyber-physical consequences affecting clinical outcomes. Such risks elevate IoMT cybersecurity from a purely technical concern to a strategic issue impacting national resilience, public trust, and institutional accountability. Therefore, vulnerability detection mechanisms must support strategic visibility across device ecosystems rather than operating solely as isolated technical tools.

2.2.2 Alignment with cybersecurity governance frameworks

Effective cybersecurity in healthcare requires alignment with established governance and regulatory standards. The proposed semantic framework enhances this alignment by mapping detected vulnerabilities to recognised cybersecurity controls, including:

- The National Institute of Standards and Technology Cybersecurity Framework (NIST CSF) (The NIST Cybersecurity Framework (CSF) 2.0, 2024), particularly functions related to Identify, Protect, Detect, and Respond.
- The ISO/IEC 27001 standard (International Organization for Standardization, 2022), specifically Annex A.12 addressing operational security controls.
- Guidance provided by the European Union Agency for Cybersecurity (ENISA) (Theocharidou & Lella, 2023) on cybersecurity in the healthcare sector.

By embedding regulatory control mappings within the ontology, the framework enables traceability between technical vulnerabilities and governance obligations, facilitating structured compliance reporting and strategic cyber risk oversight. This supports compliance reporting, audit preparation, and policy-driven security enforcement. Instead of treating compliance as a separate administrative process, the semantic model integrates it directly into the vulnerability detection lifecycle.

2.2.3 Governance-aware risk classification

The enhanced algorithm introduces governance-aware risk categorisation, classifying vulnerabilities into operational, safety, and privacy risk domains. This classification facilitates structured risk communication across technical, managerial, and executive stakeholders (Kianpour et al., 2022). For example:

- Operational risks affect system availability and service continuity.
- Safety risks impact patient health and device functionality.
- Privacy risks involve unauthorised disclosure of sensitive health information.

By formalising these relationships within the ontology, the framework supports board-level risk dashboards and strategic resource allocation decisions. This transforms vulnerability detection from a reactive technical process into a proactive governance-support mechanism.

2.2.4 Strategic value of semantic automation

In complex IoMT ecosystems, decision-makers require transparent and accountable security insights to support informed strategic and operational decisions. The integration of knowledge graphs and rule-based reasoning enables traceable inference pathways, allowing security analysts and governance stakeholders to understand how specific vulnerabilities are prioritized and how they relate to regulatory controls. By formalizing relationships between devices, vulnerabilities, risks, and compliance requirements within an ontology-driven structure, the framework enhances visibility, consistency, and accountability in cybersecurity decision-making (Ullah et al., 2025). From a strategic perspective, semantic automation functions as a force multiplier in resource-constrained healthcare environments. It enhances situational awareness, improves consistency in vulnerability assessment, reduces manual analysis overhead, and strengthens cyber resilience across distributed IoMT

infrastructures. Consequently, the proposed framework contributes not only to operational cybersecurity but also to institutional governance maturity and strategic cyber defence capability.

The integration of governance-aware risk classification, regulatory control mapping, and ontology-based compliance traceability demonstrates that semantic automation can extend beyond technical vulnerability detection. By embedding strategic oversight mechanisms directly within the reasoning pipeline, the proposed framework connects operational security processes with institutional governance objectives. This integration provides the foundation for transitioning from isolated vulnerability management toward a structured, resilient, and policy-aligned cybersecurity posture in IoMT-enabled healthcare systems.

3. Conclusion

This research presented a knowledge-driven, AI-assisted semantic framework designed to enhance vulnerability detection and cyber resilience in IoMT-enabled remote patient monitoring systems. By integrating domain ontologies, rule-based reasoning, knowledge graph representation, and external cyber threat intelligence, the proposed methodology enables structured, automated, and explainable identification of vulnerabilities, potential attack vectors, adverse cyber-physical impacts, and corresponding countermeasures. The framework advances IoMT cybersecurity by combining technical detection, explainable reasoning, regulatory alignment, and strategic risk management within a unified semantic pipeline, providing a scalable and extensible foundation for cyber defence in complex, heterogeneous healthcare environments. A semantic framework in healthcare is a crucial element in the reduction of cyber warfare exploitation for geopolitical and adversarial operations.

Grounded in a science and engineering research methodology, the framework progresses from conceptual modelling to prototype implementation, semantic integration, and validation against representative use cases. The incorporation of governance-aware risk categorisation and regulatory control mapping extends the contribution beyond purely technical automation, enabling compliance traceability and strategic risk visibility aligned with established cybersecurity frameworks. Evaluation results demonstrate improved consistency, transparency, and timeliness in vulnerability assessment compared to conventional manual approaches. By bridging semantic automation with cybersecurity governance, this work strengthens the resilience of healthcare systems increasingly recognised as critical national infrastructure, and increasingly targeted by hybrid actors.

Ethics Declaration: This study is based on conceptual modelling, simulated environments, and representative case scenarios. No real patient data, human participants, or identifiable information were used. Accordingly, formal ethical approval was not required.

AI Declaration: No artificial intelligence tools were used in the research methodology preparation, figures, tables or analysis of this manuscript.

Abstract: Automated attack simulation has emerged as an important approach for assessing the security of complex networked systems in a scalable and repeatable manner. Frameworks based on the Hierarchical Attack Representation Model (HARM), such as HARMer, support automated vulnerability discovery, attack-path generation, and attack execution. However, existing HARM-based approaches remain largely vulnerability-centric, relying on Common Vulnerabilities and Exposures (CVE) identifiers that provide limited insight into adversary behaviour. Consequently, generated attack paths are often difficult to interpret from a threat-informed defence perspective. This research investigates the integration of the MITRE ATT&CK framework into a HARM-based automated attack simulation pipeline to improve the behavioural interpretability of simulation outputs. An experimental methodology was adopted using an enhanced HARMer framework deployed within controlled and isolated environments. Vulnerability information obtained through automated scanning was used to construct HARM models representing network reachability and host-level vulnerabilities. Identified CVEs were systematically mapped to ATT&CK tactics and techniques using vulnerability descriptions, exploit documentation, and ATT&CK framework definitions. The resulting behavioural information was incorporated into attack planning and visualisation processes. To evaluate the effectiveness of the proposed enhancement, four evaluation indicators were defined: Mapping Coverage Rate (MCR), Behavioural Annotation Rate (BAR), Technique Coverage (TC), and Attack Path Preservation (APP). These indicators were used to assess the feasibility of behavioural enrichment while ensuring that the automation and scalability characteristics of the original HARMer framework were maintained. The results demonstrate that CVE-based vulnerabilities can be systematically enriched with ATT&CK semantics, enabling attack paths to be interpreted as sequences of adversary behaviours rather than isolated technical exploits. Behaviour-enhanced attack planning preserved the original path-generation logic while providing additional contextual information regarding attacker tactics and techniques. Furthermore, ATT&CK-based visualisation provided an intuitive representation of behavioural coverage across simulated attack scenarios, supporting clearer interpretation of attack activity. The study contributes a practical approach for integrating behavioural threat intelligence into HARM-based automated attack simulation. By combining vulnerability-driven attack modelling with ATT&CK-based behavioural semantics, the proposed framework advances automated red-teaming beyond purely technical exploit analysis towards more interpretable, threat-informed, and operationally relevant security assessment.

Keywords: Automated attack simulation, HARM, HARMer, MITRE ATT&CK, Threat-informed defence, Automated red-teaming, Vulnerability modelling, Adversary behaviour

1. Introduction

Modern organisations increasingly rely on complex and interconnected digital infrastructures to support critical operations. As these systems grow in scale and complexity, they present an expanded attack surface that can be exploited by adversaries employing multi-stage attack strategies. Traditional security assessment techniques, such as penetration testing and red team exercises, remain effective for identifying vulnerabilities, but they are often manual, time-consuming, and difficult to repeat consistently across different environments. These limitations have driven growing interest in automated attack simulation as a scalable and repeatable approach to security assessment.

One widely adopted approach to automated attack simulation is the Hierarchical Attack Representation Model (HARM), which represents network reachability and host-level vulnerabilities in a structured, hierarchical manner (Hong and Kim, 2012). Frameworks such as HARMer extend HARM by automating vulnerability discovery, attack modelling, and planning, enabling large numbers of attack scenarios to be generated with limited human involvement (Enoch et al., 2020). Despite these advances, HARM-based approaches remain largely vulnerability-centric. Vulnerabilities are typically represented using Common Vulnerabilities and Exposures (CVEs), which provide detailed technical descriptions but limited insight into how adversaries exploit these weaknesses as part of broader attack campaigns.

This lack of behavioural context reduces the interpretability and practical value of automated simulation outputs. Attack paths may be technically feasible but difficult to interpret in terms of adversary intent, tactics,

or techniques. The MITRE ATT&CK framework addresses this limitation by providing a behaviour-focused model of cyber-attacks, categorising adversary actions into tactics and techniques derived from real-world observations (MITRE ATT&CK®, n.d.). While ATT&CK has been widely adopted for threat modelling, detection, and reporting, it is most commonly applied after attacks or simulations have occurred. Its integration into automated attack modelling and planning processes remains limited.

This research argues that automated attack simulation can be made more interpretable and threat-informed by integrating MITRE ATT&CK directly into HARM-based automation. To investigate this, experiments were conducted using an enhanced HARMer pipeline deployed in controlled environments. Container-based deployments and scalable virtual infrastructure were used to ensure repeatability and ethical containment. The focus of the experiments was not on exploit success rates or performance metrics, but on evaluating whether behavioural context could be systematically embedded into automated simulation outputs.

1.1 Aim and Objectives

The aim of this research is to enhance HARM-based automated attack simulation by integrating the MITRE ATT&CK framework in order to improve the behavioural interpretability of simulation outputs.

The objectives of this research are to:

- Systematically map CVE-based vulnerabilities to MITRE ATT&CK tactics and techniques, enabling behavioural interpretation of identified vulnerabilities.
- Embed MITRE ATT&CK identifiers into HARM-based attack planning, allowing attack paths to reflect adversary techniques rather than isolated exploits.
- Enable ATT&CK-based visualisation of simulated attacks, providing an interpretable view of behavioural coverage across experiments.

1.2 Research Questions

This study addresses the following research questions:

1. How can CVE-based vulnerabilities be systematically mapped to MITRE ATT&CK tactics and techniques?
2. How can MITRE ATT&CK be embedded into HARM-based attack planning to improve interpretability?
3. How can ATT&CK-based visualisation represent behavioural coverage in automated attack simulation?

The remainder of this paper is organised as follows. Section 2 reviews related work, Section 3 describes the methodology, Section 4 presents and discusses the results, and Section 5 concludes the paper.

2. Literature Review

Automated attack simulation has gained increasing attention as organisations seek scalable and repeatable alternatives to manual security assessment techniques. Early approaches focused on attack graphs, which model possible sequences of exploits that an attacker could use to compromise a network. While attack graphs provide valuable insights into potential attack paths, they often suffer from scalability issues and limited ability to represent complex, multi-layered systems (Hong and Kim, 2012). These limitations motivated the development of more structured representations that could better support automated analysis.

The Hierarchical Attack Representation Model (HARM) was proposed to address these challenges by combining network reachability information with host-level vulnerability data in a hierarchical structure (Hong and Kim, 2012). In HARM, an upper-layer attack graph captures network connectivity and access relationships, while lower-layer representations model vulnerabilities on individual hosts. This separation improves scalability and allows security analysts to reason about both network-level and host-level security properties. HARM has since been applied in a range of security assessment scenarios, including vulnerability prioritisation and risk analysis.

Building on the HARM concept, Enoch et al. (2020) introduced HARMer, an automated framework that integrates vulnerability scanning, attack modelling, planning, and execution. HARMer automates the generation of attack paths by collecting vulnerability information, constructing a HARM model, and executing planned attacks in a controlled environment. This approach significantly reduces the manual effort required for security assessment and enables repeatable experimentation. However, HARMer and similar frameworks remain primarily vulnerability-driven, relying heavily on CVE identifiers and exploit availability to guide attack planning.

While CVEs provide detailed technical descriptions of vulnerabilities, they offer limited insight into adversary behaviour. CVE-based models focus on *what* is vulnerable rather than *how* attackers operate in practice. As a result, automated attack paths generated using CVE information may be difficult to interpret from a threat intelligence or defensive perspective. Analysts may struggle to understand which attacker behaviours are being simulated, how those behaviours align with real-world threats, or which defensive controls are most relevant.

The MITRE ATT&CK framework was developed to address this gap by providing a behaviour-centric knowledge base of adversary tactics and techniques derived from observed cyber-attacks (MITRE ATT&CK®, n.d.). ATT&CK organises attacker behaviour into high-level tactics, such as Initial Access or Lateral Movement, and lower-level techniques that describe specific methods used to achieve these goals. The framework has been widely adopted for threat modelling, detection engineering, and security operations, offering a common language for describing adversary behaviour.

Several studies have explored the use of MITRE ATT&CK for attack analysis and defensive evaluation. Al-Sada et al. (2024) provide a comprehensive survey of ATT&CK applications, highlighting its role in detection gap analysis, threat intelligence mapping, and security control evaluation. Other work has focused on mapping alerts, logs, or incident reports to ATT&CK techniques in order to improve situational awareness. These approaches demonstrate the value of behavioural context but typically apply ATT&CK after attacks or simulations have already occurred.

More recent research has begun to investigate the integration of ATT&CK into proactive security assessment. Jiang et al. (2025) discuss emerging approaches for incorporating ATT&CK into security testing and evaluation workflows, noting that deeper integration could support more threat-informed defence strategies. However, existing studies largely treat ATT&CK as an annotation or reporting layer rather than as a core component of attack modelling and planning.

Despite advances in both automated attack simulation and behavioural threat frameworks, a clear gap remains. HARM-based frameworks such as HARMer provide automation and scalability but lack behavioural interpretability, while ATT&CK provides rich behavioural context but is rarely embedded directly into automated attack planning. There is limited empirical work demonstrating how these two approaches can be systematically combined to produce simulation outputs that are both automated and threat-informed.

This research addresses this gap by integrating MITRE ATT&CK into a HARM-based automated attack simulation framework. By mapping vulnerabilities to ATT&CK techniques and embedding behavioural identifiers into attack planning and visualisation, the study aims to enhance the interpretability and practical relevance of automated attack simulation results.

3. Methodology

This study adopted an experimental methodology to evaluate the feasibility and effectiveness of integrating the MITRE ATT&CK framework into HARM-based automated attack simulation. The experiments were conducted in controlled environments to ensure repeatability, safety, and ethical compliance. The methodological design focused on enhancing the existing HARMer framework by embedding behavioural context into vulnerability modelling, attack planning, and result visualisation.

3.1 Experimental Environment

The experimental evaluation was conducted using an enhanced HARMer framework deployed within a controlled and isolated test environment. The design of the environment was informed by the original HARMer implementation proposed by Enoch et al. (2020), which utilised both enterprise-scale and cloud-based network infrastructures for automated attack simulation. To ensure repeatability and ethical containment, all experiments were performed on intentionally vulnerable systems within a virtualised environment.

The experimental network consisted of seven interconnected hosts representing a simplified enterprise architecture. Network reachability between hosts was controlled through predefined access rules, allowing the construction of realistic multi-stage attack paths. One host was designated as the protected target system, requiring attackers to traverse intermediate hosts before achieving the attack objective. This topology was selected because it reflects the lateral movement scenarios commonly observed in enterprise attacks.

Automated vulnerability discovery was performed against the target environment to identify known vulnerabilities. A total of 27 vulnerabilities associated with Common Vulnerabilities and Exposures (CVE) identifiers were identified across the experimental hosts. Only vulnerabilities possessing valid CVE identifiers

were included in the ATT&CK integration process, as CVE references provided a consistent basis for behavioural mapping and validation.

The environment was designed to support HARM construction by providing both network reachability information and host-level vulnerability information. This allowed attack paths generated by the framework to be analysed from both a technical and behavioural perspective. The use of a controlled environment ensured that all attack simulations remained repeatable, measurable, and ethically compliant.

3.2 Vulnerability Discovery and HARM Construction

Automated vulnerability scanning was performed against the target systems to identify known vulnerabilities. The scan results were processed to extract CVE identifiers, which formed the basis for host-level vulnerability modelling. Network topology and access relationships were combined with the vulnerability data to construct a Hierarchical Attack Representation Model.

In the constructed HARM, the upper layer represented network reachability and potential access paths between hosts, while the lower layer modelled vulnerabilities present on individual systems. This hierarchical separation enabled scalable attack path generation while preserving detailed vulnerability information required for attack planning. The HARM model served as the foundational structure upon which behavioural enhancements were applied.

3.3 Mapping CVEs to MITRE ATT&CK

To introduce behavioural context into the automated attack simulation process, vulnerabilities identified during scanning were systematically mapped to tactics and techniques within the MITRE ATT&CK framework. The mapping process was designed to enrich technical vulnerability information with behavioural semantics while preserving the underlying HARM structure and attack planning workflow.

The mapping procedure followed a rule-based methodology. First, CVE records extracted from vulnerability scanning results were analysed using information obtained from National Vulnerability Database (NVD) descriptions, exploit documentation, vendor advisories, and publicly available threat intelligence sources. Each vulnerability was then examined to determine the attacker behaviour enabled by successful exploitation. Where a clear behavioural relationship existed, the vulnerability was mapped to the most representative ATT&CK tactic and technique.

For example, vulnerabilities enabling unauthorised remote access were associated with ATT&CK techniques under the Initial Access tactic, while privilege escalation vulnerabilities were mapped to techniques within the Privilege Escalation tactic. Vulnerabilities supporting remote command execution were linked to Execution techniques, and vulnerabilities facilitating movement between hosts were associated with Lateral Movement techniques.

To maintain consistency and reduce subjective interpretation, mappings were validated against the ATT&CK framework definitions and publicly documented ATT&CK use cases. Where a vulnerability could plausibly correspond to multiple ATT&CK techniques, the technique most directly associated with the primary exploitation outcome was selected. Vulnerabilities for which behavioural intent could not be confidently determined were excluded from the mapping process to avoid speculative attribution.

The resulting mappings were stored alongside vulnerability records within the enhanced HARMer framework. This allowed ATT&CK identifiers to be propagated automatically into attack planning, attack-path generation, and behavioural visualisation. Consequently, vulnerabilities were represented not only as technical weaknesses but also as enablers of specific adversary behaviours, providing a more threat-informed representation of attack activity.

3.4 Behaviour-Enhanced Attack Planning

The original HARMer framework generates attack paths by analysing network reachability, vulnerability information, and exploit availability within a Hierarchical Attack Representation Model (HARM). While this approach effectively identifies technically feasible attack paths, the resulting outputs remain largely vulnerability-centric and provide limited insight into adversary behaviour. To address this limitation, the framework was extended to incorporate MITRE ATT&CK identifiers directly into the attack planning process.

Following the CVE-to-ATT&CK mapping stage, each mapped vulnerability was enriched with one or more ATT&CK tactics and techniques. During attack-path generation, the planner retained the original HARM-based

path-selection process but additionally associated each attack step with its corresponding ATT&CK technique. As a result, generated attack paths contained both technical exploit information and behavioural context.

The enhanced planning process therefore transformed conventional exploit chains into behavioural attack narratives. Rather than representing an attack path solely as a sequence of exploited vulnerabilities, each step could be interpreted as a specific adversary action aligned with recognised ATT&CK tactics. For example, a path beginning with remote exploitation of a public-facing service could be interpreted as Initial Access, followed by Execution, Privilege Escalation, and Lateral Movement as the attacker progressed through the network.

Importantly, the introduction of ATT&CK semantics did not alter the underlying attack-path generation logic. Path feasibility continued to be determined by network reachability, vulnerability presence, and exploit availability, consistent with the original HARMer methodology. The enhancement therefore preserved the automation and scalability benefits of HARM-based attack simulation while increasing the interpretability of generated outputs.

The resulting attack plans provided a richer representation of attacker behaviour, enabling analysts to understand not only how a compromise could occur but also which adversary tactics and techniques would be exercised during the attack sequence. This behavioural perspective supports threat-informed defence by facilitating stronger alignment between automated attack simulation and real-world adversary behaviour.

3.5 Evaluation Metrics

To evaluate the effectiveness of integrating MITRE ATT&CK into HARM-based automated attack simulation, four evaluation indicators were defined. These indicators were selected to assess behavioural enrichment while ensuring that the automation capabilities of the original HARMer framework were preserved.

The first indicator was Mapping Coverage Rate (MCR), defined as the percentage of identified CVEs that could be successfully mapped to one or more ATT&CK techniques. This metric was used to assess the feasibility of enriching vulnerability information with behavioural context.

The second indicator was Behavioural Annotation Rate (BAR), representing the percentage of generated attack-path steps that contained ATT&CK identifiers. This metric measured the extent to which behavioural information was incorporated into attack planning outputs.

The third indicator was Technique Coverage (TC), which measured the number of unique ATT&CK techniques represented across generated attack paths. Higher coverage indicated broader representation of adversary behaviour within the simulation environment.

The fourth indicator was Attack Path Preservation (APP), defined as the extent to which ATT&CK enrichment preserved the original attack paths generated by HARMer. This indicator was used to verify that behavioural integration enhanced interpretability without altering path feasibility or planning logic.

Together, these indicators provided a structured basis for evaluating behavioural enhancement while maintaining consistency with the original HARM-based attack simulation process.

4. Results and discussions

This section presents and discusses the results obtained from integrating the MITRE ATT&CK framework into a HARM-based automated attack simulation pipeline. The results focus on the behavioural interpretability of simulation outputs rather than exploit execution performance. Findings are discussed in relation to the research objectives and research questions defined in Section 1.

4.1 Results of CVE-to-ATT&CK Mapping

The first objective of this study was to determine whether vulnerabilities identified during automated scanning could be systematically enriched with behavioural information using the MITRE ATT&CK framework. The results demonstrated that a substantial proportion of CVE-based vulnerabilities could be associated with ATT&CK tactics and techniques based on their documented exploitation behaviour.

The Mapping Coverage Rate (MCR) analysis showed that behavioural enrichment was feasible across multiple categories of vulnerabilities. Vulnerabilities enabling unauthorised access to systems were commonly associated with techniques under the Initial Access tactic, while privilege escalation vulnerabilities were linked to techniques within the Privilege Escalation tactic. Similarly, vulnerabilities supporting remote code execution

were associated with Execution-related techniques, providing additional behavioural context beyond the original CVE descriptions.

Not all vulnerabilities were mapped to ATT&CK techniques. Vulnerabilities lacking sufficient behavioural detail, ambiguous exploitation outcomes, or limited supporting documentation were excluded from the mapping process. This selective approach reduced the likelihood of inaccurate behavioural attribution and ensured that ATT&CK associations remained evidence-based.

The mapping process demonstrated that vulnerability information can be systematically transformed from a purely technical representation into a behavioural representation without altering the underlying vulnerability discovery process. These findings directly address Research Question 1 by demonstrating that CVE-based vulnerabilities can be consistently associated with adversary tactics and techniques, thereby improving the interpretability of automated attack simulation outputs.

4.2 Results of Behaviour-Enhanced Attack Planning

The second objective of this research was to evaluate whether ATT&CK identifiers could be incorporated into HARM-based attack planning to improve the interpretability of generated attack paths. The results demonstrated that behavioural information could be successfully integrated into the planning process while preserving the automated path-generation capabilities of the original HARMer framework.

In the baseline HARMer approach, attack paths are represented primarily as sequences of hosts, vulnerabilities, and exploits. While these paths provide valuable technical information, they offer limited insight into the behaviour of an adversary during an attack. Following ATT&CK integration, generated attack paths retained their technical structure but additionally included behavioural annotations derived from mapped ATT&CK tactics and techniques.

The Behavioural Annotation Rate (BAR) indicated that ATT&CK information could be propagated throughout the attack-planning process, allowing attack paths to be interpreted as sequences of adversary actions rather than isolated exploit events. For example, a path could be understood as progressing through stages such as Initial Access, Execution, Privilege Escalation, and Lateral Movement, providing a clearer representation of attacker behaviour within the network.

Importantly, the Attack Path Preservation (APP) assessment showed that behavioural enrichment did not alter the feasibility of generated attack paths. Network reachability, vulnerability information, and exploit availability continued to determine path selection, consistent with the original HARMer methodology. ATT&CK integration therefore functioned as an additional semantic layer rather than a replacement for existing planning mechanisms.

These findings directly address Research Question 2 and demonstrate that ATT&CK can be embedded into HARM-based attack planning without compromising automation or scalability. The resulting attack paths provide improved behavioural interpretability while preserving the technical accuracy and repeatability of automated attack simulation.

4.3 Results Collection and Visualisation

The final objective of this research was to evaluate whether behavioural information generated during automated attack simulation could be effectively visualised using ATT&CK-based representations. Following attack-path generation, ATT&CK techniques associated with mapped vulnerabilities were aggregated and visualised using ATT&CK Navigator-style matrix views. This enabled behavioural information to be represented directly from simulation outputs rather than being added retrospectively during analysis.

The Technique Coverage (TC) evaluation demonstrated that multiple ATT&CK techniques could be represented across simulated attack scenarios, providing a consolidated view of adversary behaviour within the experimental environment. Rather than examining individual vulnerabilities or attack-path records, analysts could observe which tactics and techniques were exercised during the simulation and identify areas of behavioural coverage within the ATT&CK framework.

Figure 1 presents the HARM representation used to generate attack paths, while Figure 2 illustrates an example ATT&CK-based visualisation derived from the simulation results. The visualisation provided a concise summary of behavioural activity and enabled direct tracing between ATT&CK techniques, associated vulnerabilities, and generated attack paths.

Compared with conventional vulnerability reports or raw attack logs, ATT&CK-based visualisation offered a more intuitive representation of attacker behaviour. The approach improved accessibility for analysts and supported clearer communication of attack outcomes within a threat-informed defence context.

These findings directly address Research Question 3 and demonstrate that ATT&CK-based visualisation can serve as a practical output of automated attack simulation, enhancing the interpretability of behavioural attack data generated through HARM-based automation.

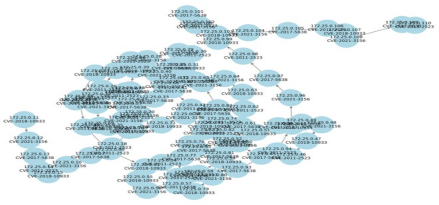

Figure 1: HARM Graph representation of vulnerabilities

4.4 Results of ATT&CK-Based Visualisation

The final set of results concerns the visualisation of simulated attacks using ATT&CK-based representations. Techniques exercised during automated attack simulations were aggregated and visualised using an ATT&CK matrix view, providing a concise overview of behavioural coverage across experiments. Figure 2 presents an example ATT&CK-based visualisation generated from the experimental results.

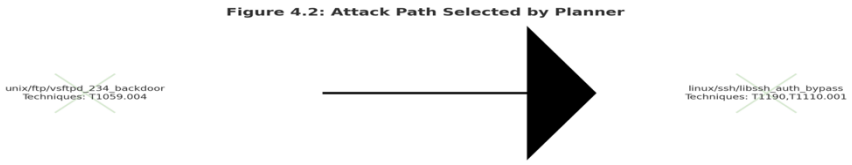

Figure 2: Attack path selected by planner

The visualisation enabled rapid identification of which adversary techniques were exercised and which areas of the ATT&CK matrix remained unrepresented. Compared to raw logs or structured output files, ATT&CK-based visualisation provided a higher-level and more intuitive summary of attack behaviour. Each highlighted technique could be traced back to specific vulnerabilities and attack path steps, supporting transparent analysis.

These results address the third research question and demonstrate that ATT&CK-based visualisation can function as a direct output of automated attack simulation rather than as a post-processing step.

4.5 Discussion

The results demonstrate that integrating MITRE ATT&CK into a HARM-based automated attack simulation framework improves the behavioural interpretability of simulation outputs while preserving the automation capabilities of the original HARMer architecture. Across the three research objectives, ATT&CK integration provided a consistent mechanism for enriching vulnerability information, attack planning, and attack visualisation with adversary-focused context.

A key observation from the study is that traditional HARM-based attack simulation and ATT&CK-based threat modelling address complementary aspects of security assessment. HARM provides an effective mechanism for modelling network reachability and identifying technically feasible attack paths, whereas ATT&CK provides a structured representation of adversary behaviour. By combining these approaches, the enhanced framework retains the technical accuracy of vulnerability-driven attack simulation while providing behavioural explanations for simulated attack activity.

Compared with baseline HARMer, the enhanced framework offers several advantages. First, vulnerabilities can be interpreted as enablers of adversary techniques rather than isolated technical weaknesses. Second, generated attack paths can be understood as behavioural attack narratives that align with recognised ATT&CK tactics. Third, ATT&CK-based visualisation provides a higher-level representation of attack activity that supports communication between technical analysts, security managers, and decision-makers.

Importantly, the integration of ATT&CK did not require modification of the core HARM modelling principles or automated planning mechanisms. Network reachability analysis, vulnerability discovery, and attack-path

generation remained unchanged, demonstrating that behavioural enrichment can be achieved without sacrificing scalability or repeatability. This finding is particularly important because it suggests that behavioural threat intelligence can be embedded within existing automated attack simulation frameworks rather than requiring entirely new architectures.

The findings therefore support the argument that automated red-teaming can evolve beyond vulnerability-centric assessment towards a more threat-informed approach that reflects how adversaries operate in practice. By linking technical vulnerabilities with behavioural intelligence, the proposed enhancement contributes to more interpretable and operationally relevant security assessment.

4.6 Limitations and Future Work

Although the results demonstrate the feasibility of integrating MITRE ATT&CK into HARM-based automated attack simulation, several limitations should be acknowledged. First, the experimental evaluation was conducted within controlled and isolated environments designed to support repeatability and ethical testing. While suitable for demonstrating proof of concept, these environments may not fully capture the complexity, scale, and dynamic behaviour of large enterprise networks.

Second, the CVE-to-ATT&CK mapping process relied on publicly available vulnerability descriptions, exploit documentation, and ATT&CK definitions. Although validation procedures were applied to reduce ambiguity, some level of expert judgement remained necessary when selecting the most representative ATT&CK technique. Future work could investigate automated mapping approaches using threat intelligence platforms and machine learning techniques to improve consistency and scalability.

Third, the evaluation focused primarily on behavioural interpretability rather than operational performance. The study demonstrated that ATT&CK integration could enrich attack simulation outputs, but it did not measure analyst decision-making, detection effectiveness, or defensive outcomes. Future research could incorporate user studies to evaluate whether ATT&CK-enhanced simulations improve analyst understanding and support more effective threat-informed defence activities.

Finally, future work could extend the framework to support ATT&CK sub-techniques, adversary emulation profiles, and larger-scale cloud environments. Such enhancements would provide a more detailed representation of attacker behaviour and enable broader evaluation of behavioural attack simulation across diverse operational scenarios.

5. Conclusion

This paper presented an experimental investigation into the integration of the MITRE ATT&CK framework within a HARM-based automated attack simulation environment. The motivation for the study was the limited behavioural interpretability of existing vulnerability-centric attack simulation approaches, which often represent attacks as sequences of technical exploits without clearly conveying adversary behaviour.

To address this limitation, the HARMer framework was enhanced by incorporating ATT&CK tactics and techniques into vulnerability modelling, attack planning, and simulation visualisation. Vulnerabilities identified through automated scanning were systematically mapped to ATT&CK techniques, enabling behavioural information to be embedded directly within the attack simulation process. The resulting attack paths retained the technical accuracy of HARM-based modelling while providing additional insight into attacker objectives, tactics, and techniques.

The evaluation demonstrated that behavioural enrichment could be achieved without altering the underlying attack-path generation mechanisms of HARMer. Mapping Coverage Rate (MCR), Behavioural Annotation Rate (BAR), Technique Coverage (TC), and Attack Path Preservation (APP) provided a structured framework for assessing the effectiveness of ATT&CK integration. The findings showed that behavioural context could be consistently incorporated into automated attack simulation outputs while preserving automation, repeatability, and scalability.

The principal contribution of this research is the demonstration that behavioural threat intelligence can be embedded directly into HARM-based automation rather than applied only as a post-analysis activity. By combining vulnerability-driven attack modelling with ATT&CK-based behavioural semantics, the proposed approach advances automated red-teaming towards a more interpretable and threat-informed form of security assessment.

Future research should evaluate the approach within larger and more diverse environments, investigate automated ATT&CK mapping techniques, and assess the impact of behaviour-enhanced simulation on analyst decision-making and defensive planning. Such developments would further strengthen the practical applicability of ATT&CK-integrated automated attack simulation for modern cybersecurity operations.

Cyber Power Through Propagation Control

Gregory P. Carpenter
CW PENSEC, LLC
Independent Researcher

gregory.carpenter@cwpensec.com

Abstract: Enterprise cyber defense operates in telemetry-saturated environments, yet major incidents continue to escalate through rapid, large-scale propagation. Failure rarely stems from lack of visibility; it reflects inability to suppress spread across interconnected systems before compromise becomes self-sustaining. Contemporary cyber operations exploit trust relationships and identity infrastructure to convert initial access into distributed control, overwhelming response capacity despite extensive sensing. This exposes a measurement gap: defenders lack a defensible method for assessing whether an environment can contain propagation once intrusion begins. We propose a cyber-epidemiological model of intrusion propagation that treats the enterprise as a population distributed across a directed graph of trust, privilege, and service relationships. Compromise is modeled as a dynamic process rather than a binary outcome, and defensive cyber operations are treated as endogenous counterforces that directly compete with attacker-driven spread. We formalize a compartmental S-E-I-Q-R model in which susceptible, exposed, infectious, quarantined, and recovered states correspond to operational phases of cyber campaigns, including foothold establishment, activation, lateral movement, isolation, and remediation. This formulation extends prior cyber-epidemic models by explicitly incorporating enterprise identity architecture and active defensive response dynamics central to modern cyber conflict. Building on this model, we derive a cyber reproduction number, R_o, using a next-generation matrix approach. R_o represents the expected number of secondary infectious compromises generated by a single infectious node in an otherwise susceptible environment. Interpreted as an environmental threshold, R_o distinguishes escalation from containment: when R_o exceeds unity, propagation outpaces defensive action; when R_o falls below unity, containment dominates and campaigns tend to collapse. R_o characterizes environmental susceptibility to sustained cyber operations, independent of attacker identity or tooling. To operationalize the framework without experiments, the paper proposes a telemetry-driven method for estimating model parameters from standard security operations center and incident response artifacts. The result is a defensible analytic lens linking security architecture, defensive operations, and campaign outcomes, supporting prioritization decisions that constrain adversary freedom of action, reduce coercive cyber power, and strengthen deterrence by denial at both enterprise and national scales.

Keywords: Cyber epidemiology, Reproduction number (R_o), Attack graph modelling, Propagation thresholds, Security telemetry, Cyber resilience

1. Introduction

Cyber defenses operating in telemetry-rich environments still fail at scale. Modern enterprises deploy endpoint detection and response, network telemetry, identity and access logging, cloud audit trails, case management systems, and threat intelligence feeds. This is a campaign-level failure rather than a single-host problem. Adversaries require time and exploitable trust pathways to convert initial access into durable operational reach.

The unresolved question is structural: can the environment suppress propagation once compromise begins? In other spread-dynamic domains, the central analytic question is threshold: does the system dampen escalation or amplify it until externally constrained (European Systemic Risk Board 2020)?

This paper proposes a cyber-epidemiological model of intrusion propagation that treats the enterprise as a population, compromise as a dynamic state, and defensive operations as endogenous counterforces. Prior compartmental models of malware propagation (Mishra and Saini 2007; Mishra and Jha 2010; Hernández-Guillén et al. 2017; Hernández-Guillén et al. 2019; Chernikova et al. 2023) often assume homogeneous infection and limited integration of identity architecture or live defensive response. Contemporary intrusions instead exploit identity systems, delegated privilege, and shared infrastructure as primary propagation substrates, while defenders respond under active contest.

The core contribution is adapting the epidemiological reproduction number to cyber defense. We adapt R_0 as an environment-level threshold for escalation versus containment. As in epidemiology, R_0defines a threshold: when $R_0 > 1$, spread exceeds response capacity and campaign-scale compromise becomes structurally likely; when $R_0 < 1$, defensive action suppresses spread.

This framing links defensive posture to systemic resilience. Architecture shapes transmission; defensive operations shape infectious duration and recovery. Environments that suppress propagation constrain adversary freedom of action, whereas persistently elevated R_o indicates structural vulnerability.

We develop a formal theoretical model without empirical validation. No experiments are conducted. The objective is to define a mathematically grounded framework, derive a cyber reproduction number using a next-generation matrix approach, and specify a telemetry-driven parameter estimation method using standard SOC and incident-response data.

2. Background and Related Work

2.1 Cyber-Epidemiological Modeling of Malware and Compromise

The analogy between biological epidemics and malware propagation is established. Compartmental models, including SIR, SEIR, and variants, have been applied to worms and malicious objects to capture latency, reinfection, and countermeasure effects (Mishra and Saini 2007; Mishra and Jha 2010; Hernández-Guillén et al. 2017). Subsequent work incorporated stability analysis and explicit defensive action, showing that containment and recovery reshape propagation dynamics (Hernández-Guillén et al. 2019). Recent studies further formalize behavioral assumptions and forecasting (Chernikova et al. 2023; Kovtun et al. 2024; Zhou et al. 2023).

A persistent limitation is operational mapping. Many models assume homogeneous substrates and collapse compromises into a single infected state, underrepresenting staged activation, identity-mediated transmission, live containment, and asymmetric recovery. This work retains the epidemiological framing but defines compartments and parameters in cyber-operational terms, enabling direct mapping from identity-mediated transmission signals and endogenous response actions observed in logs and incident timelines to model dynamics.

2.2 Attack Graphs, Lateral Movement, and Structural Pathways

In parallel, cybersecurity research uses graph-based abstractions to enumerate adversary pathways through attack graphs and lateral movement analysis. These models formalize reachability, privilege relations, and exploit chaining to surface structural exposure and prioritize mitigation. Recent work emphasizes identity relationships, particularly within enterprise directory services, as dominant enablers of lateral movement (Herranz Oliveros et al. 2024), alongside broader efforts to analyze cyber related graphs at scale (Kuikka et al. 2024).

The limitation is threshold reasoning. Attack graphs describe how campaigns may progress but provide no environment level criterion for when progression becomes self-sustaining under active defense. This work treats the graph as the transmission substrate and adds population dynamics to capture nonlinear escalation and containment.

2.3 Kill Chains, TTP-Centric Models, and Campaign-Scale Behavior

Operational cyber defense is commonly structured around kill chains, adversary TTPs, and stage-based sequencing. These frameworks organize detection and response but emphasize procedural progression rather than spread. Campaign outcomes hinge on whether initial access expands into distributed control, driven by propagation opportunity and defensive tempo rather than technique presence alone.

Campaign oriented research embeds cyber operations within structured representations to analyze adversary behavior at scale (Lee and Choi 2023). Automated attack emulation shows how multi-step operations can be planned and scaled, accentuating the need for models that represent propagation under adversarial optimization (Wang et al. 2024).

2.4 Cyber Resilience, Systemic Risk, and Architectural Defense

Cyber resilience frames security as the capacity to sustain operations, recover, and adapt under attack. Resilience engineering emphasizes architecture, response capability, and systemic dependencies as outcome determinants (Bodeau et al. 2011; Ross et al. 2021). Incidents escalate when shared infrastructure, including identity services, backups, and management planes, is compromised and recovery becomes protracted.

Systemic risk modeling offers an analogy. Instability is typically threshold driven rather than a linear accumulation of local failures. The European Systemic Risk Board cyber crash model emphasizes propagation and amplification across interdependent systems (European Systemic Risk Board 2020), motivating cyber defense equivalents to reproduction thresholds.

Modern security architecture guidance reflects this logic. Zero Trust treats implicit trust as the primary risk vector and advocates continuous verification, least privilege, segmentation, and assumed breach (NIST 2020).

In propagation terms, these controls reduce transmission probability, constrain reachability, and shorten infectious periods through faster containment.

2.5 Incident Handling, SOC Measurement, and Telemetry as Instrumentation

Cyber defense is executed through detection, response, and recovery. NIST incident handling guidance formalizes lifecycle management and emphasizes disciplined timelines, containment, and recovery validation (NIST 2025). Empirical SOC studies show effectiveness depends on decision and execution latency as well as detection capability (Forsberg and Frantti 2023).

Here, telemetry is instrumentation for system level inference. The objective is not attribution but estimating whether containment and recovery suppress propagation, preventing localized compromise from becoming campaign sustaining.

2.6 Summary of the Gap

A common limitation persists. Epidemic models capture nonlinear spread but lack enterprise-operational grounding. Attack graphs expose structure but provide no escalation threshold. Resilience frameworks emphasize architecture yet lack a scalar containment criterion. The reproduction-number framework integrates these perspectives by coupling graph structure, compartmental dynamics, and a threshold metric grounded in operational telemetry.

3. A Compartmental Epidemiological Model of Cyber Propagation

Reasoning about cyber intrusion at campaign scale requires moving beyond binary notions of compromise toward explicit modeling of intrusion progression. Cyber operations do not transition directly from access to impact; they evolve through foothold establishment, activation, lateral movement, and continuous interaction with defensive response. These dynamics map naturally to compartmental epidemiological models when defining compartments in operational cyber terms rather than biological analogy. Prior work has applied compartmental abstractions to malware and worm propagation, but typically assumes homogeneous infection and offers limited treatment of enterprise identity architecture and live defensive response dynamics central to modern intrusions (Mishra and Jha 2010; Hernández-Guillén et al. 2019; Chernikova et al. 2023).

3.1 System Representation

We model the enterprise as a directed graph $G = (V, E)$, where nodes represent hosts, identities, services, or control-plane elements, and edges represent feasible pathways for adversary action. Edges encode operational reachability and may arise from network connectivity, authentication trust, shared credentials, delegated privilege, or application-level access. This abstraction treats network topology and identity architecture as a single propagation substrate. While graph-based representations are well established in attack-graph and lateral-movement modeling, they are rarely integrated with population-dynamics frameworks capable of expressing system-level threshold behavior (Herranz-Oliveros et al. 2024; Kuikka et al. 2024).

At time t, each node occupies one of five compartments:

- **Susceptible (S):** Reachable nodes with exploitable conditions, such as exposed services, valid credentials, or trust relationships, that remain uncompromised.
- **Exposed (E): Nodes where initial access has been established via credential capture, payload delivery, or execution, but not yet used for propagation.**
- **Infectious (I):** Nodes actively leveraged for lateral movement, privilege escalation, command and control, or coordinated action.
- **Quarantined (Q):** Nodes isolated by defensive action, including segmentation enforcement, account restriction, or endpoint containment.
- **Recovered (R):** Nodes remediated to remove attacker access and reduce near-term susceptibility through reimaging, patching, or credential rotation.

Prior cyber-epidemic models frequently collapse compromise into a single infected state, obscuring dwell time, staged activation, and defensive interventions observed in real incidents (Mishra and Saini 2007; Hernández-Guillén et al. 2017). The compartmental distinctions introduced here reflect operational phases encountered in defensive cyber operations and incident response.

Notation Summary

$G = (V, E)$: Directed enterprise graph
S, E, I, Q, R: Compartment states
β: Effective transmission rate
σ: Activation rate
γ: Isolation rate
ρ: Recovery rate
R_0: Cyber reproduction number
$\rho(\cdot)$: Spectral radius

3.2 Transition Dynamics

Cyber propagation reflects a continuous contest between attacker-driven expansion and defender-driven isolation and recovery. This interaction is captured through four parameters governing transitions among compartments, each grounded in observable cyber-operational processes:

- **Effective transmission rate** (β)**:** The probability that an infectious node compromises a susceptible neighbor per unit time, conditioned on connectivity, vulnerability, and privilege.
- **Activation rate** (σ)**:** The rate at which exposed nodes transition to active use for propagation, reflecting attacker staging and dwell time.
- **Defensive isolation rate** (γ)**:** The rate at which infectious nodes are detected and isolated through defensive action.
- **Recovery or hardening rate** (ρ)**:** The rate at which compromised nodes are remediated such that attacker access is removed and near-term susceptibility reduced.

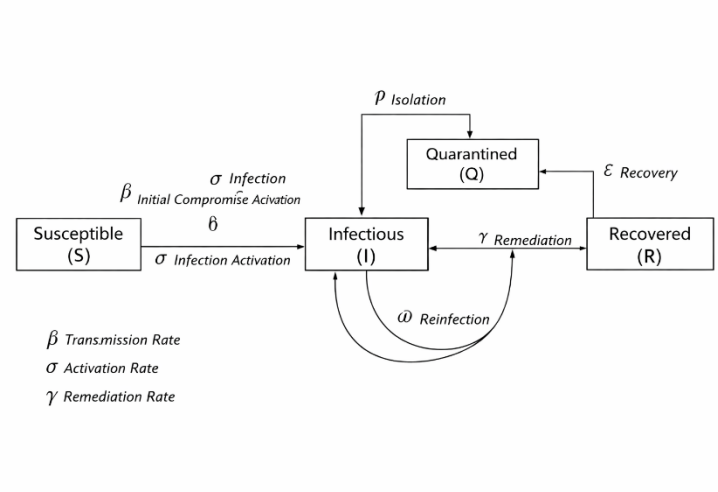

Figure 1: Compartmental model of cyber-attack propagation

In discrete time, the system is expressed as:

$$\begin{aligned} S_{t+1} &= S_t - \beta S_t I_t \\ E_{t+1} &= E_t + \beta S_t I_t - \sigma E_t \\ I_{t+1} &= I_t + \sigma E_t - (\gamma + \rho) I_t \\ Q_{t+1} &= Q_t + \gamma I_t \\ R_{t+1} &= R_t + \rho I_t \end{aligned}$$

Mixing and graph-structure note. The term $\beta S_t I_t$adopts a mean-field approximation, treating interaction between infectious and susceptible nodes as homogeneous across feasible edges. In practice, enterprise environments exhibit degree heterogeneity, privilege stratification, and control-plane dependencies represented by $G = (V, E)$. The mean-field formulation is used here to isolate threshold behavior and preserve tractable parameter estimation from operational telemetry. Section 4 interprets the resulting R_0 as an environment-level threshold under this approximation. Network-heterogeneous extensions, including spectral-radius–weighted thresholds, are left for future development.

3.3 Defensive Cyber Operations as Endogenous Forces

A defining feature of this framework is treating defensive cyber operations as endogenous to propagation rather than external mitigations applied after compromise. Detection, isolation, and remediation are modeled as forces that directly compete with attacker-driven spread at each timestep. Campaign escalation therefore depends not on detection in isolation, but on whether defensive action shortens the effective infectious period sufficiently to suppress further propagation.

From a security-architecture perspective, key model parameters are shaped by structural design choices. Flat networks, excessive privilege, and permissive trust relationships increase effective transmission β; segmentation, least-privilege, and constrained delegation reduce β by limiting reachable attack paths. Investment in SOC staffing, automation, and response orchestration primarily affects isolation $\gamma$by reducing time to containment. Together, operations and architecture act on complementary components of the propagation dynamic, consistent with cyber resiliency engineering that treats security as an emergent property of system design and adaptive response (Bodeau et al. 2011; Ross et al. 2021).

3.4 Campaign-Scale Interpretation

At campaign scale, the model captures behavior characteristic of contemporary offensive cyber operations. Advanced actors depend on conditions that sustain movement over time. Once multiple infectious nodes are established, propagation accelerates nonlinearly as lateral actions compound and response capacity saturates. This dynamic is poorly represented by linear kill-chain or TTP-centric models. By contrast, it emerges naturally in a population-dynamics formulation that explicitly models competing rates of propagation and containment.

4. Derivation and Interpretation of the Cyber Reproduction Number (R_o)

These transition dynamics provide the basis for deriving an environment-level propagation threshold, formalized in the following section as a cyber reproduction number. While compartmental dynamics describe how cyber intrusions evolve, defenders require a scalar measure that indicates whether a campaign is likely to escalate or collapse. In epidemiology, this role is served by the basic reproduction number, R_o. We adapt this construct to cyber defense by defining a cyber reproduction number that captures environmental susceptibility to propagation.

4.1 Definition and Derivation of Cyber R_o

Cyber $R_0$is defined as the expected number of secondary infectious nodes generated by a single infectious node introduced into an otherwise susceptible environment. Crucially, R_0 is a property of the defensive environment rather than a specific attacker, malware family, or exploit chain. As in epidemiology and systemic risk analysis, R_0serves as a threshold quantity: when it exceeds unity, propagation becomes self-sustaining; when it falls below unity, containment dominates and escalation collapses (European Systemic Risk Board 2020).

Following standard epidemiological practice, R_0 is derived using a next-generation matrix approach. Let the vector of epidemiologically active compartments be defined as

$$\boldsymbol{x} = \begin{bmatrix} E \\ I \end{bmatrix},$$

where Erepresents exposed nodes that have established an initial foothold but are not yet propagating, and Irepresents infectious nodes actively used for lateral movement and campaign expansion. Only infectious nodes generate new exposures.

The system dynamics are decomposed into two components: a matrix F, capturing the rate at which new exposures are generated, and a matrix V, capturing transitions among infected states and removal through isolation and recovery. Linearizing the system around the disease-free equilibrium yields:

$$\boldsymbol{F} = \begin{bmatrix} 0 & \beta \\ 0 & 0 \end{bmatrix}, \boldsymbol{V} = \begin{bmatrix} \sigma & 0 \\ -\sigma & \gamma + \rho \end{bmatrix}.$$

The next-generation matrix is defined as:

$$\boldsymbol{K} = \boldsymbol{F}\boldsymbol{V}^{-1},$$

and the cyber reproduction number is given by:

$$R_0 = \rho(\boldsymbol{K}),$$

where $\rho(\cdot)$denotes the spectral radius.

For this compartmental structure under the mean-field mixing assumption introduced in Section 3.2, the dominant eigenvalue admits a closed-form expression:

$$R_0 = \frac{\beta}{\gamma + \rho}.$$

In structured networks, the threshold generalizes to a spectral-radius form:

$$R_0 = \rho(\boldsymbol{FV}^{-1})$$

where the transmission component is weighted by the adjacency structure of G. The scalar expression presented here isolates the balance between transmission and removal while preserving analytic tractability and practical identifiability from telemetry data.

This result has a direct operational interpretation. The escalation threshold is governed by the balance between effective transmission and removal through containment and recovery. While the activation rate σinfluences the tempo of campaign progression, it does not alter the threshold condition itself. As a result, cyber R_0separates architectural exposure, captured by β, from defensive response capacity, captured by $\gamma$and ρ.

Interpreted operationally, $R_0 > 1$indicates that each compromised node generates more than one additional infectious node before isolation or remediation, making campaign-scale escalation structurally likely.

Conversely, $R_0 < 1$indicates that defensive action suppresses propagation faster than attackers can expand it, causing campaigns to collapse regardless of individual techniques or tooling. This threshold behavior mirrors empirical observations from large-scale ransomware and advanced persistent threat campaigns, where containment failure is systemic rather than exploit-specific (Lee and Choi 2023).

4.2 Relationship to Offensive and Defensive Cyber Operations

From an offensive perspective, cyber operations can be interpreted as increasing effective R_o. Techniques such as credential dumping, trust abuse, and living-off-the-land tooling increase $\beta$and σ while minimizing γ. Campaign success depends not on stealth alone but on sustaining R_o above unity long enough to generate irreversible effects (Wang et al. 2024).

From a defensive perspective, operations aim to suppress R_o. Detection, response automation, and remediation primarily act on γ and ρ, while architectural controls act on β. This clarifies the strategic value of architecture: reducing propagation potential before an incident begins rather than racing spread after compromise.

4.3 Cyber Power and Structural Resilience

At a strategic level, R_o provides a quantitative lens on cyber power and resilience. Environments that consistently maintain R_o below unity are inherently resistant to coercion through cyber means. Environments with high R_o invite repeated exploitation regardless of attacker identity. This framing aligns with national cyber strategy emphasis on sustained operational advantage rather than episodic compromise (U.S. Department of Defense, 2023; The White House 2023).

4.4 Practical Implications

The value of R_0 lies in decision support. Interval estimates are sufficient to determine threshold regime classification. By shifting focus from individual alerts to systemic thresholds, R_0 supports a more strategically grounded approach to defensive cyber operations.

5. Parameter Estimation from Security Telemetry

This paper proposes a telemetry-driven approach for parameterizing the cyber propagation model. The objective is to define a defensible and implementable method by which a security operations function can estimate model parameters in practice. In epidemiology and systemic risk analysis, model utility depends less on precise parameter values than on whether estimates are sufficiently grounded to distinguish regimes, specifically whether $R_0 > 1$or $R_0 < 1$, and to support comparative assessment of controls (Kovtun et al., 2024). The same principle applies to cyber defense.

The parameters of interest, effective transmission probability (β), exposure-to-compromise activation rate (σ), defensive isolation rate (γ), and recovery or hardening rate (ρ), are not abstract constants. They are operational properties of an environment, observable through standard defensive telemetry including identity logs, endpoint telemetry, network flow records, and incident timelines. The estimation workflow treats the SOC as the measurement instrument and the enterprise as the population under observation.

5.1 Telemetry Sources and Observability

Most enterprises already collect the data required to estimate these parameters, though rarely for system-level inference.

Identity and access telemetry: Authentication and authorization logs from directory services and cloud identity providers provide evidence of credential misuse, lateral authentication, privilege escalation, and anomalous access patterns. Directory artifacts such as group membership changes, delegated rights, and trust relationships expose structural conditions that influence transmission likelihood.

Endpoint and EDR telemetry: Process creation, command-line execution, module loading, and network connections indicate post-compromise activation (E→I), lateral tooling, and propagation attempts. Containment actions including host isolation and process termination provide timestamps relevant to defensive isolation (γ).

Network telemetry: NetFlow, firewall, proxy, DNS, and segmentation enforcement logs provide visibility into reachable paths, attempted connections, beaconing behavior, and blocked propagation, informing both graph construction and effective connectivity.

Incident response artifacts: Case management systems, playbook execution logs, and analyst notes provide high-fidelity timing data for detection-to-isolation and isolation-to-recovery intervals. Post-incident reviews support validation of assumptions and interpretation of anomalous dynamics.

These sources align with established guidance for incident handling, SOC performance measurement, and cyber resilience, though they are typically applied tactically rather than analytically (NIST, 2025; Forsberg and Frantti 2023; Ross et al. 2021).

Observability remains imperfect. Attackers may operate below logging thresholds, and telemetry coverage varies across environments. Accordingly, the estimation approach prioritizes conservative inference and explicitly accounts for uncertainty to avoid overstating defensive capability.

5.2 Estimating Effective Transmission (β)

In this framework, β denotes the probability that an infectious node generates a new exposed node per unit time along feasible edges of the enterprise graph $G = (V, E)$.

Let:

- $\mathcal{E}_t \subseteq E$ denote the set of feasible directed edges active during observation interval t,
- C_t denote the number of observed feasible propagation attempts along edges in $\mathcal{E}_t$,
- X_t denote the number of newly established exposed nodes attributable to infectious sources during t.

Under a Bernoulli transmission assumption along feasible contacts, conditional on observability, the maximum-likelihood estimator for β is:

$$\hat{\beta} = \frac{\sum_t X_t}{\sum_t C_t}$$

This estimator corresponds to a binomial likelihood model over observed feasible contacts:

$$X_t \sim \text{Binomial}(C_t, \beta)$$

Bias and Observability Adjustment

In practice, C_t is subject to undercount bias due to incomplete telemetry and unobserved propagation attempts. Let $\pi \in (0,1]$ denote estimated contact observability. A conservative lower-bound estimator is:

$$\hat{\beta}_{\text{lower}} = \frac{\sum_t X_t}{\sum_t C_t}$$

An upper-bound estimator adjusts for incomplete contact observability:

$$\hat{\beta}_{\text{upper}} = \frac{\sum_t X_t}{\pi \sum_t C_t}$$

where π may be estimated from logging coverage metrics, red-team ground truth exercises, or retrospective detection rates.

Thus β is treated as an interval parameter:

$$\beta \in [\hat{\beta}_{\text{lower}}, \hat{\beta}_{\text{upper}}]$$

Stratified Transmission

Because transmission probability varies by identity tier, network segment, and control-plane function, stratified estimators are recommended:

$$\hat{\beta}_k = \frac{\sum_t X_{t,k}}{\sum_t C_{t,k}}$$

where $k$indexes structural strata of G.

5.3 Estimating Activation (σ)

The activation rate σ captures the transition from exposure to infectious activity (E→I), reflecting the delay between initial foothold establishment and active propagation. σ can be estimated from the interval between first evidence of foothold establishment and first observed lateral or coordinated activity. Where telemetry resolution is limited, bounding σ rather than point estimation is often sufficient for threshold analysis.

σ is strongly shaped by offensive tradecraft. Hands-on-keyboard intrusions exhibit longer activation periods, while automated or monetization-driven campaigns shorten activation windows. Comparative analyses show ransomware operations consistently activate faster than espionage-focused intrusions, informing σ as an expectation of operational tempo rather than attribution (Lee and Choi 2023).

5.4 Estimating Defensive Isolation *(γ)*

The isolation rate γ represents the transition from infectious to quarantined state (I→Q), capturing the combined effects of detection, analyst decision-making, and containment execution. Operationally, γ reflects the inverse of the effective infectious duration prior to isolation.

Let $t_I^{(k)}$denote the timestamp of first observable infectious activity for incident instance k, and let $t_Q^{(k)}$denote the timestamp at which isolation or containment action is completed. Define the infectious duration prior to isolation as:

$$\Delta t_\gamma^{(k)} = t_Q^{(k)} - t_I^{(k)}.$$

Under an exponential removal assumption, a consistent estimator for γ is:

$$\hat{\gamma} = \frac{1}{\Delta \bar{t}_\gamma},$$

where $\Delta \bar{t}_\gamma$is the mean infectious-to-isolation interval across observed cases.

In practice, γ may be decomposed into detection latency, decision latency, and execution latency. This decomposition supports targeted operational improvement, as investments in automation, playbook refinement, or analyst staffing affect distinct components of isolation time. Empirical SOC studies indicate that reducing decision and execution latency frequently produces greater threshold impact than marginal improvements in detection accuracy (Forsberg and Frantti 2023; NIST 2025).

5.5 Estimating Recovery and Hardening (*ρ*)

The recovery rate ρ captures the transition from compromised to remediated state (I→R or Q→R), representing removal of adversary access and reduction of near-term susceptibility through reimaging, credential rotation, patching, and closure of exploited trust pathways.

Let $t_Q^{(k)}$denote the timestamp at which node $k$is isolated and let $t_R^{(k)}$denote the timestamp at which verified remediation and hardening are completed. Define the containment-to-recovery interval as:

$$\Delta t_\rho^{(k)} = t_R^{(k)} - t_Q^{(k)}.$$

Assuming exponential recovery dynamics, a consistent estimator for ρ is:

$$\hat{\rho} = \frac{1}{\Delta \bar{t}_\rho},$$

where $\Delta \bar{t}_\rho$is the mean isolation-to-recovery interval across observed cases.

Recovery duration varies substantially by asset class. Identity providers, backup infrastructure, and management planes frequently exhibit longer recovery intervals and disproportionately influence systemic resilience.

Stratified estimation by system criticality or functional tier is therefore recommended to prevent high-impact assets from being diluted in aggregate averages (Bodeau et al. 2011; Ross et al. 2021).

As with γ, recovery intervals may be right-censored when remediation remains ongoing or validation is delayed. Interval-based reporting and conservative classification prevent overstating effective hardening capacity.

5.6 Handling Uncertainty and Bias

Telemetry-based estimation is inherently biased by incomplete observability. Attackers may evade detection, defenders may identify compromise retrospectively, and logging coverage is uneven across systems. These effects introduce undercount bias in transmission events and right-censoring in isolation and recovery intervals.

To address these limitations, parameters are represented as bounded intervals rather than single-point estimates:

$$\beta \in [\beta_{\min}, \beta_{\max}], \gamma \in [\gamma_{\min}, \gamma_{\max}], \rho \in [\rho_{\min}, \rho_{\max}]$$

Bounds are derived from conservative event classification, earliest plausible infection timestamps, and latest plausible containment or remediation timestamps. Sensitivity analysis is conducted by propagating parameter intervals through the reproduction-number expression:

$$R_0 = \frac{\beta}{\gamma + \rho}$$

yielding an uncertainty interval:

$$R_0 \in \left[R_{0,\min}, R_{0,\max}\right]$$

Local Sensitivity

Local sensitivity of the threshold to parameter perturbation is given by:

$$\frac{\partial R_0}{\partial \beta} = \frac{1}{\gamma + \rho}$$
$$\frac{\partial R_0}{\partial \gamma} = -\frac{\beta}{(\gamma+\rho)^2}$$
$$\frac{\partial R_0}{\partial \rho} = -\frac{\beta}{(\gamma+\rho)^2}$$

These expressions permit ranking of architectural versus operational control leverage under perturbation.

The operational objective is regime classification rather than precise prediction. If $R_{0,\min} > 1$, escalation is structurally robust to uncertainty. If $R_{0,\max} < 1$, containment is structurally robust. When the interval spans unity, architectural or operational adjustments should be prioritized until threshold classification becomes unambiguous. This approach aligns with established robustness practice in epidemiology and systemic risk modeling (Kovtun et al. 2024).

5.7 Cyber Threat Intelligence as Parameter Refinement

Within this framework, cyber threat intelligence refines parameters rather than assigns attribution. Intelligence on tooling, preferences, and operational tempo informs expectations for β and σ, while lessons from prior campaigns inform *γ* and *ρ*. This positions intelligence as an input to defensive posture management rather than retrospective explanation, aligning with campaign-centric views of cyber operations (Lee and Choi, 2023).

5.8 Practical Deployment Considerations

The approach is deployable within existing SOC environments and requires no new sensors or experimental instrumentation. It relies on retrospective incident reconstruction and reassessment following architectural change. The model does not depend on attribution; it evaluates structural propagation conditions independent of actor identity or tooling.

The objective is a defensible determination of whether an environment is predisposed to outbreak-scale compromise. When R_o exceeds unity, the environment should be treated as pre-failed and architectural intervention prioritized. When $R_o < 1$, defensive operations can shift from crisis response toward sustained resilience.

6. Conclusion

Enterprise cyber defense failures are rarely attributable to insufficient visibility. They emerge when propagation outpaces containment once compromise is established. This paper reframes the problem as a threshold condition rather than isolated detections, advancing a cyber-epidemiological model that treats intrusion propagation as a population-level dynamic governed by architecture, trust relationships, and defensive response capacity.

By formalizing a compartmental S–E–I–Q–R model grounded in operational cyber states, this work extends prior cyber epidemic models to reflect contemporary enterprise conditions, particularly identity-driven propagation and active defensive intervention. The derivation of a cyber reproduction number, R_o, introduces a scalar, environment-level metric that discriminates between escalation and containment. When R_o exceeds unity, campaign-scale compromise becomes structurally probable independent of attacker tooling or intent. When R_o is driven below unity, defensive operations dominate and campaigns tend to fail.

The value of R_o lies not in precise prediction but in decision support. The telemetry-driven estimation approach presented here demonstrates that defenders can approximate propagation thresholds using existing operational data, without experiments, attribution, or additional sensing infrastructure. This enables comparative evaluation of architectural controls, response tempo, and recovery effectiveness, each directly linked to campaign-level outcomes.

Operationally, the framework shifts emphasis from alert pursuit to managing propagation potential. Strategically, it frames cyber resilience as a property of system design rather than reactive capability. Environments that sustain elevated R_o remain vulnerable to coercive cyber operations regardless of attribution or intent.

By introducing a mathematically grounded yet operationally implementable threshold lens, this work provides a missing analytical bridge between security architecture, defensive cyber operations, and campaign-scale risk. The result is a defensible basis to assess containment versus escalation before adversaries convert access into sustained control.

Ethics Declaration: This research is theoretical and conceptual in nature. It involved no human participants, operational systems, or experimental interventions, and therefore did not require ethical approval.

AI Declaration: AI-based tools were used to prepare this manuscript, supporting language refinement and structural clarity. All technical content, modeling decisions, analysis, and conclusions were developed, reviewed, and validated by the author, who retains full responsibility for the work.

Securing the AI Revolution: A Maturity Framework for Trustworthy and Resilient Software

Jami M. Carroll
Prisidian Security Solutions, Inc.; Somerset, MA; USA

jcarroll@prisidian.com

Abstract: Traditional software-development maturity models—CMMI, Agile, and DevOps—were designed for deterministic, human-centric processes and struggle to govern the probabilistic, data-driven nature of AI systems. As organizations embed Artificial Intelligence (AI) across the Software Development Life Cycle (SDLC), these legacy frameworks lack structures to manage AI-specific risks such as governance, security, data provenance, and model behavior. Accelerated digital transformation and cloud-native delivery amplify the consequences of unmanaged AI adoption, exposing firms to systemic security and supply-chain vulnerabilities. This study uses constructivist Glaserian Grounded Theory to synthesize evidence from industry practitioners, academic researchers, FFRDCs, and scholarly literature, thereby creating an AI-centric software maturity framework. This study develops a five-level AI maturity framework for developing trustworthy and resilient software, grounded in secondary data from industry documents, academic papers, and FFRDC reports using Glaserian Grounded Theory. The framework is empirically derived to identify recurring patterns across sectors, yet it is explicitly presented as a modifiable theory rather than a statistically generalizable model. Future work will validate the framework through primary research – interviews, surveys, and observations to capture informal decision-making practices omitted from the secondary corpus. This five-stage AI adoption model offers a progressive, security-oriented maturation through the stages of 1) Foundational Awareness & Governance—establish AI policies, ethics, and baseline literacy; (2) Experimentation & Initial Integration—enable controlled AI pilots in isolated environments; (3) Integrated Development—embed AI within CI/CD pipelines and business workflows; (4) Proactive Security & Trusted AI—scale AI with threat detection, adversarial testing, and model security; and (5) Adaptive Excellence—achieve continuous, closed-loop optimization of AI performance, security, and impact. These findings leverage coaching, Vygotsky's zone of proximal development, and Kolb's experiential learning to reconcile rapid delivery with trustworthy, resilient software while aligning governance, automation, and security across all stages reduces systemic risk, strengthens supply-chain resilience, and enables sustainable AI transformation.

Keywords: Artificial intelligence, Capability maturity model, Software engineering, Zone of proximal development, Experiential learning

1. Introduction

Disclaimer: All statements of fact, opinion, or analysis expressed are those of the author. The views and opinions expressed herein by the author do not represent the official policies or positions of the United States (U.S.) Department of Defense (DoD), U.S. Navy, or other agencies or departments of the U.S. government and are solely representative of the views of the author. This does not constitute an official release of DoD or Navy information.

1.1 Background and Motivation

Artificial Intelligence (AI) is reshaping software engineering by automating core SDLC tasks—requirements analysis, code generation, testing, deployment, and monitoring. AI-assisted tools such as code copilots, automated test frameworks, and self-optimizing pipelines now permeate the SDLC, delivering productivity gains and scalability while introducing risks from probabilistic behavior, opaque decision-making, and rapid automation (Sarker 2025). Historically, software development maturity models guided readiness and alignment with organizational goals; however, accelerated AI integration challenges their relevance for AI-driven environments. Sarker's review of ACM, IEEE, and industry studies (2020-2025) reports a 55.8 % productivity boost but a 40–50 % rise in security vulnerabilities in AI-generated code, largely due to developers relinquishing control. With global adoption rates of 62–84 %, AI must augment rather than replace developers, necessitating new upskilling and collaboration strategies.

MITRE (Bloedorn et al., 2023) emphasizes that AI-driven systems are critical to economic stability, national security, and public trust; insecure dependencies can propagate vulnerabilities through supply chains, making security a structural constraint. Effective AI integration requires structured maturity frameworks and experienced champions to guide organizations through five adoption stages, drawing on Kolb's experiential learning and Vygotsky's zone of proximal development to scaffold transitions. This research explores how these pedagogical models inform AI-centric maturity frameworks, fostering technical competence, critical thinking, and ethical awareness essential for responsible AI deployment. Aligning governance, automation, and security

across all stages can reduce systemic risk, strengthen supply-chain resilience, and achieve sustainable AI transformation.

1.2 Problem Statement

Many firms have adopted the CMU SEI blend of CMMI, Agile, and DevOps to improve processes. Though this hybrid can deliver gains, it carries conflicting assumptions (Glazer et al., 2008). Two decades on, these frameworks still misalign with AI-enabled systems that are probabilistic, data-driven, and increasingly autonomous. Recent updates treat AI tools merely as efficiency layers, overlooking their transformative effects on system behavior, security perimeters, and governance (Rajab & Alnouki, 2025). As organizations move from experimentation to operationalization and autonomous optimization, legacy models cannot capture AI-specific risks—uncontrolled code generation, weakened architectural guarantees, accelerated supply-chain vulnerabilities, and adversarial manipulation. AI's rapid decision amplification widens gaps in governance, accountability, and security controls (Ozkaya et al., 2025). Consequently, without an AI-centric maturity framework that integrates governance, experimentation, operationalization, proactive security, and continuous adaptation, firms lack a structured path to secure AI adoption, impeding readiness assessment, workforce alignment, and sustained trust in AI-driven software engineering.

1.3 Research Objective and Thesis

This study illuminates how maturity evolves in AI-enabled software development and why CMMI, Agile, and DevOps fail to govern it. Rather than extending legacy models, we construct a structurally apt framework grounded in cross-sector practice (Mohajan & Mohajan, 2022). Using Glaserian Grounded Theory on secondary data from industry reports, academic literature, FFRDC outputs, and research unit findings, we show that maturity arises from the co-evolution of governance structures, secure automation mechanisms, and human oversight. The analysis reveals recurrent failure patterns and adaptive strategies missing from current models, leading to a five-level AI-centric framework that redefines maturity as a security-anchored, socio-technical progression guiding organizations from fragmented experimentation to adaptive, resilient, and trustworthy AI-enabled software development.

1.4 Structure of the Paper

The paper is structured as follows: Section 2 reviews related work and critically assesses the limitations of existing software-development maturity models in AI-driven engineering. Section 3 details our methodology, highlighting secondary data use and Glaserian Grounded Theory analysis. Section 4 presents emergent findings, revealing AI-native maturity dimensions derived from the grounded study. Section 5 introduces a five-level AI-centric framework, explicating each level as an emergent theoretical construct. Section 6 discusses implications for software engineering practice, security architecture, and policy development. Section 7 outlines study limitations and future research directions. Finally, Section 8 concludes by summarizing key contributions and underscoring the importance of AI-native maturity models for securing the AI revolution.

2. Background and Related Work: Limitations of Existing Software Development Maturity Models

Software development maturity models have long guided organizational capability, process improvement, and alignment with strategic goals, emerging to address growing complexity and the need for repeatability, predictability, and quality. Their foundational assumptions—human-written, deterministic code governed by linear or iterative processes—now clash with AI's pervasive integration across the SDLC. This section surveys CMMI, Agile, and DevOps maturity models, critiquing their structural limitations for AI-driven engineering. By focusing on architecture rather than implementation details, it shows why these models fail to govern probabilistic, autonomous, and security-sensitive AI-enabled systems.

2.1 Capability Maturity Model Integration (CMMI)

CMMI boosts performance through disciplined process management, stressing standardization, measurement, and continuous improvement. Its governance, compliance, and predictability strengths dominate regulated, high-assurance sectors. Yet CMMI's deterministic assumptions—specifying, controlling, and auditing behavior via fixed processes—make it ill-suited for AI, which is treated merely as a supporting tool rather than a system actor. Consequently it lacks mechanisms for AI-specific risks such as model drift, data dependency, probabilistic outputs, and autonomous decisions. Procedural controls that fit human-paced cycles misalign with AI's rapid

artifact evolution, creating bureaucratic bottlenecks or informal workarounds that erode governance. (Eliseo et al., 2025).

2.2 Agile Maturity Models (Scrum, Kanban, XP)

Agile models—Scrum, Kanban, XP—were created to counter plan-driven rigidity by promoting adaptability, collaboration, and rapid feedback. Their iterative delivery suits early AI experimentation, especially when AI assists backlog prioritization, code generation, and testing. Yet they provide little governance or architectural guidance, deferring security to informal discipline. As AI-generated code and autonomous decisions scale, the absence of explicit accountability, supply-chain risk, and model-security controls becomes critical, since Agile assumes human reviewers remain primary—a premise broken when AI takes on those roles (Abrar et al., 2025).

2.3 DevOps Maturity Models

DevOps models blend development and operations through automation, CI/CD, and shared reliability, prioritizing deployment frequency, MTTR, and observability—well suited to cloud-native microservices. In AI-driven engineering these pipelines become autonomous, using AI for testing, monitoring, and remediation. However, maturity is judged mainly by automation depth rather than trustworthiness or controllability. AI-influenced deployments blur accountability, exposing gaps in adversarial protection, dependency poisoning, and memory safety from automated code generation, thus creating unchecked automation (Mamun, 2024).

2.4 Cross-Model Synthesis and Structural Gaps

CMMI, Agile, and DevOps focus on governance, adaptability, or automation assuming a stable human-centric control plane. They lack mechanisms for AI that autonomously generates, modifies, and deploys code at machine speed. These frameworks treat governance, security, and oversight sequentially, a division that collapses when AI permeates the SDLC, causing security failures from misaligned automation and control. This structural gap necessitates an AI-centric maturity model intertwining governance, security, and oversight as co-evolving socio-technical realities (Abrar et al., 2025; Mamun, 2024).

3. Research Methodology

3.1 Methodological Orientation: Secondary Data Grounded Theory

This study employs Secondary Data Grounded Theory, following Glaserian principles to inductively generate theory from existing documents, literature, and archives instead of primary data. The method suits AI-driven software development maturity, which spans diverse sectors and governance regimes. Classic Grounded Theory emphasizes theory emergence, minimal preconception, and constant comparison regardless of source. Thus, secondary materials provide an empirical base where patterns, categories, and relationships surface, aligning with Glaser's view that grounded theory can validly arise from "any data" when the analytic process remains inductive, comparative, and theory-generating (Mohajan & Mohajan, 2022).

3.2 Data Corpus and Source Selection

The study's corpus is exclusively secondary, spanning AI-enabled software engineering, security governance, and maturity modeling across sectors. It comprises industry documents (public reports, white papers, architectural guides, incident analyses, practitioner texts on AI-assisted development, DevSecOps pipelines, and operational security controls); academic literature (peer-reviewed journals, conference papers, research unit outputs on AI software engineering, secure SDLCs, supply-chain risk, and socio-technical dynamics); FFRDC (public notes on AI security, assurance, resilience, and risk in high-assurance contexts); and standards artifacts (archival records from bodies such as AI risk management and software assurance). Theoretical sampling guided iterative inclusion until saturation, ensuring no new properties or relationships emerged.

3.3 Analytic Procedure

Data analysis followed classic Grounded Theory's constant comparison, avoiding preset codes. Line-by-line open coding revealed recurring concepts—AI adoption, governance gaps, security failures, automation risk, and organizational responses—while keeping codes conceptual. Continuous comparison linked incidents across documents, sectors, and institutions, uncovering similarities, differences, and boundary conditions. Theoretical coding merged related categories into higher-order relationships, showing AI-driven software maturity arises from interactions among governance, automation, security mechanisms, and human oversight. No axial coding or predefined model was imposed; categories gained relevance through repeated emergence (Mohajan & Mohajan, 2022).

3.4 Theoretical Emergence, Framework Development, Rigor, Trustworthiness, and Limitations

The five-level AI-centric maturity framework emerged inductively from grounded analysis, charting progress from unstructured experimentation to adaptive, secure AI-enabled development. Its levels are conceptual stages—not prescriptive checklists—highlighting empirically observed transitions, recurring failure modes, and why legacy models miss AI-native behaviors. Rigor rested on theoretical saturation, constant comparison, and avoidance of preexisting frameworks; findings offer analytical generalization across sectors. A limitation is reliance on publicly documented practices, potentially omitting informal or classified implementations.

4. Emergent Findings: AI-Native Dimensions of Software Development Maturity

Grounded analysis of secondary data from industry docs, academia, FFRDCs, and standards revealed a core concern shared by AI-enabled software engineering adopters: scaling automation while preserving trust, security, and control. This led to recurring theoretical categories that explain why legacy maturity models (CMMI, Agile, DevOps) fail to govern AI systems and how maturity unfolds uniquely in AI-native environments. These categories transcend traditional distinctions, highlighting AI-specific socio-technical dynamics.

4.1 Current Industry Practices

Organizations currently embed ISO/IEC 42001, NIST AI RMF, and other fragmented standards into governance boards, risk registries, decision pathways, or DevSecOps pipelines in a piecemeal way. Whether applied to a fintech's provenance dashboard, a public-sector AI charter, or an automotive manufacturer's security-by-design process, this ad-hoc approach leaves firms in a haphazard position regarding governance, security, data provenance, and model behavior.

4.2 Governance Lag as a Systemic Failure Mode

Across sectors, data show a consistent lag: AI tools—coding assistants, automated testing, and pipeline automation—are deployed before formal governance is in place. Legacy maturity models presume that policy precedes technology, yet AI-enabled development reverses this order. The result is reactive governance that emerges only after experimentation, leaving AI systems running without clear accountability, acceptable-use policies, or risk ownership. This structural lag correlates with downstream security breaches, inconsistent code quality, and opaque decision-making (Birkstedt et al., 2023).

4.3 Acceleration-Induced Security Risk Amplification

A second emergent category is security risk amplification driven by AI-accelerated velocity. AI-assisted development compresses traditional SDLC timelines through automated code generation, test creation, and deployment. However, this acceleration magnifies design flaws, unsafe dependencies, and insecure defaults. Comparative analysis across documents shows that vulnerability introduction rates do not fall proportionally with AI assistance; instead, vulnerabilities spread faster and more widely. Current maturity models focus on delivery speed, deployment frequency, or process adherence, yet they lack mechanisms to assess how risk scales nonlinearly in AI-augmented environments. True security maturity here emerges not from faster pipelines, but from the capacity to detect, constrain, and correct AI-amplified failure modes in near real time (Habbal et al., 2024).

4.4 Erosion of Architectural and Memory Safety Boundaries

The analysis also surfaced a recurring erosion of architectural software pattern coherence and memory safety guarantees in AI-assisted development environments. AI-generated code often optimizes for local correctness or syntactic validity while overlooking broader architectural constraints, security invariants, or language-specific safety considerations. Across multiple sources, organizations relying heavily on AI-generated code without enforcing memory-safe language standards or architectural validation experience increased defect density and security debt. This finding highlights a mismatch between AI tooling capabilities and legacy maturity models, which assume that developers remain the primary agents of architectural and memory safety enforcement. In AI-driven systems, these responsibilities increasingly shift to tooling, policy, and pipeline-level controls (Xu et al., 2025).

4.5 Automation Without Accountability in AI-Augmented Pipelines

Another emergent category is automation without accountability, particularly in mature DevOps environments transitioning toward autonomous operations. AI-enabled pipelines increasingly make deployment, rollback, and remediation decisions without clear human authorization boundaries or auditability mechanisms. Grounded

analysis indicates that organizations often equate pipeline automation maturity with operational excellence, even as decision authority becomes opaque. This pattern exposes a structural gap: existing maturity models emphasize automation outcomes but do not account for who or what is accountable for AI-mediated decisions. Trustworthy maturity emerges only when accountability mechanisms evolve alongside automation capability (Baqar et al., 2025).

4.6 Human Oversight and Workforce Readiness as Limiting Factors

The data consistently identifies human oversight capacity and workforce readiness as limiting factors in AI maturity progression. As AI systems assume more cognitive and operational tasks, developers and security professionals transition from creators to supervisors of AI behavior. However, legacy maturity models do not account for this role transformation. Organizations lacking AI literacy, model interpretability skills, and adversarial awareness struggle to detect subtle failures, model drift, or security degradation. Maturity in AI-driven environments therefore emerges not solely from tooling sophistication, but from the alignment of human expertise with AI system behavior (Sarker, 2025).

4.7 Synthesis of Emergent Findings

Collectively, these findings indicate that maturity in AI-enabled software development is not linear, tool-driven, or process-bound, but emergent, arising from the interaction of governance, automation, security mechanisms, and human oversight. The recurring failure patterns observed across sectors explain why CMMI, Agile, and DevOps maturity models—each optimized for deterministic systems—are structurally misaligned with AI-driven software engineering. These emergent categories directly inform the five-level AI-centric maturity framework presented in Section 5, which reconceptualizes maturity as a security-anchored, adaptive progression rather than a static process benchmark.

5. The Five-Level AI-Centric Software Development Maturity Framework

Grounded analysis revealed that AI-enabled software development matures not through incremental optimization but via distinct qualitative shifts in governance, operationalization, security, and adaptation. These shifts form a five-level AI-centric maturity framework that traces the journey from fragmented, tool-driven adoption to resilient, trustworthy, and adaptive engineering. As a theoretical model rather than a prescriptive roadmap, the framework captures stable configurations of governance, automation, security controls, and human oversight at each level, with advancement driven by resolving recurring failure modes observed across industry, academia, FFRDCs, and research units.

5.1 Level 1: Foundational Awareness and Governance (Baseline Literacy)

At Level 1, organizations grow aware of AI's influence yet lack systematic governance. Adoption is ad hoc, driven by individual developers or isolated teams experimenting with AI coding tools, testing frameworks, or analytics. Findings show a focus on policy drafting, ethical considerations, and baseline literacy to manage early uncertainty and risk. Governance bodies—AI councils or steering committees—emerge mainly to set acceptable use, data handling, and accountability limits. Security controls remain inherited from pre-AI SDLCs, not yet tailored to AI risks. This stage curbs unbounded experimentation but does not yet support safe operationalization; advancement requires recognition that governance alone cannot mitigate expanding AI risks.

5.2 Level 2: Experimentation and Initial Integration (Pilot Stage)

At Level 2, organizations launch controlled AI pilots in sandboxed or isolated settings, embedding tools like chatbots, code assistants, or test generators into limited workflows to gauge productivity and feasibility. Grounded data reveals recurring issues—poor data quality, inconsistent outputs, and hidden security assumptions in AI artifacts. Governance structures from Level 1 are tested against reality, exposing gaps in policy enforcement and risk ownership. Maturity progresses only when firms move beyond proof-of-concept metrics to address how AI outputs align with architectural constraints, security requirements, and downstream automation.

5.3 Level 3: Integrated Development (Operationalization & CI/CD)

Level 3 marks the shift from experimentation to operational AI-enabled production. Tools become integral to development environments, CI/CD pipelines, and business workflows, boosting deployment velocity. Grounded findings identify new systemic risks: AI-generated code scales faster than human review, vulnerabilities spread through pipelines, and architectural drift is harder to detect. Without AI-aware security controls and memory-safety enforcement, organizations accrue rapid technical and security debt. Maturity at this stage arises

when AI tooling is treated as production infrastructure, demanding the same rigor, monitoring, and security guarantees that other critical systems require.

5.4 Level 4: Proactive Security and Trusted AI (Scaling)

At the Proactive Security level, organizations explicitly recognize AI as both a security enabler and a security subject. AI is applied to threat detection, anomaly analysis, and predictive vulnerability identification, while parallel efforts focus on securing AI models, data pipelines, and decision logic. Grounded analysis highlights the introduction of adversarial testing, red teaming, and continuous security verification as defining characteristics of this level. Accountability mechanisms evolve to ensure that automated decisions remain observable, explainable, and auditable. This level stabilizes AI-driven scaling by aligning automation speed with adaptive security controls, enabling organizations to expand AI usage without proportionally increasing systemic risk.

5.5 Level 5: Adaptive Excellence (Transformation)

Level 5, Adaptive Excellence, marks the point where AI-enabled development is self-correcting, resilient, and strategically embedded. Organizations run closed-loop systems in which performance, security, and behavioral feedback continuously refine models and processes. Grounded data shows that maturity here is defined by autonomous optimization bounded by robust governance and human oversight: AI systems evolve as integral organizational assets rather than mere tools. Human roles shift to strategic supervision, ethical judgment, and resilience planning, ensuring that scaling AI automation does not erode trust, security, or control.

5.6 Framework Implications

The five-level maturity framework explains why organizations stagnate or regress when attempting to extend legacy maturity models into AI-driven environments. Progression requires resolving qualitatively different challenges at each level rather than accumulating incremental process improvements. By grounding maturity in emergent security and governance dynamics, this framework provides a structurally appropriate lens for understanding trustworthy and resilient AI-enabled software development.

5.7 Results

To illustrate the applicability of this maturity framework, three industry examples include: 1) a public-sector data analytics firm adopting AI governance checkpoints at the Governance level to plan their corporate waypoints; 2) a fintech startup integrating model provenance during the Security stage to ensure fiduciary responsibilities to their clients; and 3) a manufacturing firm applying continuous learning pipelines within the Model Behavior level. These examples parallel the structured approaches of AI-driven software development recommended by Ozkayo et al., 2025 and Sarkar, 2025.

6. Implications for Practice and Policy

The five-level AI-centric maturity framework has significant implications for software engineering practice, security architecture, and policy development. Rather than offering prescriptive controls, the framework explains why certain practices succeed or fail as organizations progress through AI adoption. These implications suggest that trustworthy and resilient AI-enabled software development emerges from structural alignment between governance, automation, security, and human oversight—not from isolated technical interventions.

6.1 Implications for Software Engineering and Security Practice

For practitioners, AI maturity demands more than tooling; it requires evolving governance and security mechanisms. Deploying AI-assisted development without robust controls amplifies risk, rendering deterministic SDLC practices—post-hoc code review or episodic testing—insufficient as artifacts scale at machine speed. Security architecture must shift to systemic, pipeline-level enforcement: memory safety, architectural validation, and dependency provenance must be baked into automated workflows. Engineers transition from implementers to AI supervisors, acquiring skills in model risk assessment, anomaly interpretation, and adversarial reasoning. The framework also warns that skipping levels—adopting advanced automation prematurely—often triggers maturity regression, as unresolved governance gaps erode security and trust at scale.

6.2 Implications for Organizational Leadership and Workforce Development

At the organizational level, AI maturity is a human and governance challenge as much as it is technical. Leadership models designed for traditional development often lack clear ownership of AI decisions, leaving accountability, risk acceptance, and ethics ambiguous. Workforce readiness becomes a bottleneck when AI

systems gain operational autonomy; without targeted investment in AI literacy, interpretability, and adversarial awareness, teams depend on outputs they cannot fully evaluate, increasing fragility and eroding trust. Leaders must align incentives, training, and organizational design with AI's evolving role; treating governance as mere compliance instead of a strategic capability prevents adaptive excellence.

6.3 Implications for Policy, Standards, and Regulatory Frameworks

For policymakers and standards bodies, current assurance frameworks often fail to capture AI-native development dynamics. Regulations premised on static codebases, human-authored artifacts, or linear SDLCs cannot govern systems that learn continuously, generate code autonomously, and optimize in real time. The five-level framework provides a maturity-based lens, enabling policies that scale expectations with organizational capability rather than enforcing one-size-fits-all mandates. Such stage-aligned regulation balances innovation, security, and compliance—especially for critical infrastructure—while also demanding support for governance structures, workforce transformation, and ongoing adaptation mechanisms.

6.4 Summary of Implications

Collectively, these implications reinforce the central finding of this study: trustworthy and resilient AI-enabled software development cannot be achieved through incremental extensions of legacy maturity models. Instead, it requires a reconceptualization of maturity that reflects how AI reshapes risk, responsibility, and control across software systems. The five-level AI-centric maturity framework provides a grounded explanatory model that can inform practice, guide organizational transformation, and shape adaptive policy approaches in the AI era.

7. Limitations and Future Research

As with all theory-building research, this study is subject to several limitations that inform the interpretation of its findings and outline directions for future inquiry. These limitations stem primarily from the methodological choices and the evolving nature of AI-driven software engineering.

7.1 Methodological Limitations

This study relies exclusively on secondary data and Grounded Theory analysis of industry documents, academic papers, FFRDC reports, and archives. While Glaserian methods suit a fast-moving, multi-sector field, they depend on the availability and transparency of published material; informal practices, classified deployments, or undocumented behaviors may be omitted. The secondary nature also precludes probing ambiguities or clarifying the intent behind documented practices, unlike interview-based research that can interrogate decision-making rationales. Nevertheless, the broad, cross-sector dataset mitigates this limitation by highlighting recurring patterns rather than isolated anecdotes.

7.2 Scope and Generalizability

The resulting five-level maturity framework is offered as an analytical and explanatory model, not a statistically generalizable or prescriptive standard. While the framework reflects patterns observed across diverse sectors, it does not claim universal applicability to all organizational contexts, particularly those operating under unique regulatory, cultural, or technological constraints. Furthermore, the framework emphasizes security-centric maturity dynamics and may not capture all dimensions relevant to organizations focused primarily on economic optimization or consumer-facing innovation. These boundaries reflect deliberate scope decisions aligned with the research problem.

7.3 Temporal Limitations

AI technologies, development practices, and regulatory environments are evolving rapidly. As a result, some practices observed in the data corpus may become obsolete or transformed over time. Consistent with classic Grounded Theory, the framework is presented as a modifiable theory that should evolve as new data and practices emerge. Longitudinal studies are required to assess how organizations transition between maturity levels over time and whether additional stages or sub-dimensions emerge as AI capabilities mature.

7.4 Directions for Future Research

Future work should validate and extend this framework through primary research—interviews, ethnography, or surveys—to capture decision-making nuances and informal practices missing from secondary data. Quantitative studies could operationalize maturity dimensions into measurable indicators, enabling cross-organizational benchmarking and longitudinal tracking. Domain-specific adaptations for high-assurance sectors such as critical infrastructure, defense, and regulated industries warrant exploration. Finally, research should assess how the

model aligns with emerging AI governance standards, risk frameworks, and regulatory regimes, ensuring its relevance to evolving policy landscapes.

Future work will complement this secondary-data grounded theory with primary research through interviews, surveys, or ethnographic observations to capture the decision-making this data corpus could not reveal since many organizations guard their AI maturity data as proprietary or in some case classified because of the client confidentiality, competitive advantage, or national security interests at stake. Organization masking will continue to be used as this emergent framework is expanded to respect the fiduciary and security constraints that limit publicly available data.

7.5 Alignment With Standards and Policies

In unison with the Directions for Future Work, benchmarking the five-level maturity model against emerging AI governance standards (ISO 42001, NIST AI RMF) and risk management frameworks will verify compliance and gaps where each maturity level will decompose standard requirements traceability with measurable metrics. This will identify policy-gap analysis across high-trust sectors such as critical infrastructure, defense, and regulated industries to better tune the model for more common use across multiple sectors to ensure alignment with emerging AI governance standards, risk assessment systems, and regulatory regimes in changing geopolitical environments.

7.6 Summary

These limitations do not reduce the contribution of this study but a vector for ongoing future research. By offering an empirically grounded, AI-centric maturity framework, this work provides a foundation for future empirical validation, theoretical refinement, and practical application as AI-driven software engineering continues to evolve.

8. Conclusion

The rapid embedding of AI into software development has reshaped design, production, and security practices, revealing that legacy maturity models—CMMI, Agile, DevOps—are structurally ill-fit for AI's probabilistic, autonomous, and machine-speed dynamics. This study used secondary data and Glaserian Grounded Theory to inductively uncover recurring patterns across industry, academia, and FFRDCs, showing that AI maturity depends on the interplay of governance, automation, security, and human oversight rather than mere process compliance. The resulting five-level AI-centric framework explains progression from fragmented experimentation to adaptive, resilient, and trustworthy development, positioning security and trust as emergent socio-technical properties. By offering a flexible, theory-driven lens that adapts to evolving AI practices, the framework supports empirical validation, policy design, and organizational transformation essential for a secure AI future.

Apache Daffodil for Network Traffic Validation

Ben Cavanagh and Stephen Taylor
Dartmouth College, Hanover NH, USA

benjamin.y.cavanagh.27@dartmouth.edu
stephen.taylor@dartmouth.edu

Abstract: This paper explores the relative merit of Apache Daffodil for the automated generation of real-time network traffic validators associated with military vehicles. Daffodil is an "open-source implementation of the Data Format Description Language (DFDL)" which converts between natively formatted data and Extensible Markup Language (XML), JavaScript Object Notation (JSON) or other structures based on predefined schemas. Daffodil can also automatically generate executable parsers, and it is the efficacy and maturity of this facet of the technology for traffic validation that is our primary interest. Military vehicles have traditionally used compact protocols, such as Space Packet Protocol (SPP), MIL-STD-1553, or Controller Area Network bus (CAN bus), to enable real-time validation and limit malicious implants embedded in normal traffic. Over time, message traffic has grown increasingly complex due to increases in performance and use of commercial-off-the-shelf networking technologies leveraging Ethernet and TCP/IP protocols. Messages may now include mission-specific or recursively defined data embedded in the payload fields of variable-length packets. Consequently, it is valuable to assess Daffodil's ability to handle both existing formats and representative payload data within this emerging context. Here we directly compare DFDL schemas with equivalent grammars expressed in an extended version of Backus-Naur Form (xBNF) and Hammer to assess its expressive capability and succinctness. To assess the maturity of its validator generator, we compared Daffodil to the industry-standard Bison tool (for xBNF) and Hammer library. Though the comparison is based on numerous formats, here we present three examples: JSON numbers—a simple recursive data format; Micro Air Vehicle Link (MAVLink) messages—non-trivial byte-oriented traffic; and generic SPP messages—a bit-oriented, fixed-size format. Unfortunately, Daffodil's automated parser generation capabilities are currently neither mature nor robust. Daffodil is primarily useful for analysing fixed-length formats or variable-length components which follow descriptive header fields. Daffodil parsers can elegantly check compact bit-wise protocol formats, which is more difficult using Bison and some versions of Hammer. Daffodil is currently of limited utility in analysing recursive or non-prefixed formats such as JSON. Writing DFDL manually appears significantly more verbose and error-prone than both xBNF and Hammer.

Keywords: Apache Daffodil, Bison, Hammer, Parser generation, Traffic validation, Secure parsing

1. Introduction

Many organizations handle sensitive data and files relating to military missions, trade secrets, intellectual property, private personal data, and/or classified projects (NBAR, 2021). Traditionally, these organizations have been well advised to implement an air gap that physically isolates computers containing sensitive information from the Internet to protect against theft. Unfortunately, air gaps come with a substantial cost in productivity and assume that professional staff, with the expertise to handle sensitive information, are co-located. Consequently, individual air, space, and ground vehicles increasingly rely upon standard networking technologies to link embedded control systems with sensors, actuators, and human-machine interfaces through industry standard buses (e.g., CAN, J1939, MIL-STD-1553, USB) and communications interfaces (e.g., Gigabit Ethernet, OpenVPX, and PCIe). Network connected personal devices—phones, tablets, and laptops—are increasingly used to manage and interact with these systems. Though conceptually air-gapped, these systems are intermittently connected with military installations to provide mission parameters, or to effect maintenance and upgrades. Network boundary protections are used during these activities, but threat vectors including unintended connections, insiders, zero-day exploits, supply chain interdiction, and persistent implants can circumvent such protections (Kushner, 2013).

To combat these threats, byte-by-byte validation of message data can be implemented below the network stack—within the kernel, hypervisor, or underlying hardware—to ensure data is well-formed and contains reasonable values relative to the intended mission. Such validation makes use of *parsers*, which implement well-defined *grammars* representing the acceptable syntactic structure of messages. Traditionally, parsers match data to grammatical rules and generate parse trees, or structural representations. Validators must only establish that the input is consistent with the grammar and return a binary valid/invalid result. Beyond pure syntactic validation, more complex programs may also verify that data falls within reasonable threshold values, for example regarding the physical status of a vehicle within its intended mission. This paper explores the relative capabilities of Bison, Hammer, and Apache Daffodil with regards to the generation of validation parsers as part of a larger network traffic security toolchain.

1.1 Automated Parser Generation

Parser generators are tools that take a grammar as input and automatically generate a program that implements the associated parser. Here we consider three alternative approaches to automated parser generation—Bison (Levine, 2009), Hammer (Bratus et al, 2016), and Apache Daffodil (W3C, 2012)—to assess their relative strengths for network traffic validation. All three tools can operate on both textual (i.e. ASCII) and binary data. Though we have explored many grammars, we present observations here in the context of three formats that exemplify our findings: JavaScript Object Notation Numbers (JNUM) (ECMA, 2017), Micro Air Vehicle Link (MAVLink) (Dronecode Foundation, n.d.) protocol messages, and Space Packet Protocol (SPP) messages (CCSDS, 2020). JSON numbers involve recursively structured, byte-oriented data; MAVLink uses prefixed variable-length byte-oriented messages, and SPP messages use bit-oriented fields.

1.1.1 Bison

Bison is the most mature and widely used parser generator. It accepts context free grammars (CFGs) and primarily generates two classes of parser: generalized left-to-right (GLR) and the more restrictive look-ahead left-to-right (LALR). Input CFGs are expressed as a set of parsing rules in Backus-Naur Form (BNF) (Backus et al, 1960). Each rule expresses how a non-terminal symbol in the grammar is composed of terminal symbols such as ASCII characters (e.g. 'a'), binary values expressed in hexadecimal (e.g. '\xF5'), or other non-terminal symbols. Recursive rules can describe *sequences* of symbols, and multiple rules associated with the same non-terminal provide *choice* in how to parse a particular construct.

Though GLR parsers are more capable, LALR parsers are sufficient for validating a wide variety of communication protocols and file formats. Their simplicity allows them to be realized by a simple push-down automaton—a finite state machine employing a single stack to store symbols while parsing the input stream. The state machine relies on two core operations: shift—saving an input symbol to the stack—and reduce—the application of a grammar rule to detect a structure and reduce the symbols on the stack. The order in which shift and reduce operations are applied to the input is based on a collection of parsing tables derived from the grammar, usually referred to as Action/Goto tables (Aho, Sethi, and Ullman, 1988). These tables map the current state of the automaton to a next state based on the symbol read from the input stream.

Unfortunately, Bison's version of BNF cannot natively express common constructs in communication protocols such as strings (e.g. 'true'), wildcard values matching any input byte (often written *), fixed width data types (e.g. uint_64, int_16 etc.) in big- or little-endian formats, or ranges of values (e.g. ['a'-'f'] representing a character between 'a' and 'f' inclusive). Consequently, here we use an extended form of BNF (xBNF) to simplify each grammar using these additional notations (Taylor and Meise, 2021). The extended form is implemented as a preprocessor, written in Bison.

1.1.2 Hammer

Hammer is modern "parser combinator" library developed under the DARPA SafeDocs program. The library provides a collection of formally-defined base parsers and rules, designated with an *H_RULE()* construct, which are combined to build more complex parsers—all expressed in the C programming language. The more complex parser combinators *h_sequence()* and *h_choice()* allow sequences of parsers and choices between alternative parsers, respectively, to be composed. The resulting parsers are provably correct by construction. The Hammer library provides a collection of back ends that allow different parsing algorithms to be employed, including Packrat, providing recursive descent parsing, and LALR, providing bottom-up look-ahead parsing. Unfortunately, only the Packrat back end supports bit-oriented combinators, which can directly parse bit fields instead of having to pad each field to byte length through preprocessing. Further, the LALR back end does not support the little-endian combinators needed for MAVLink. As such, the Hammer versions of the JNUM parser used here make use of the LALR back end to match that of xBNF, while the MAVLink and SPP parsers use the Packrat back end.

1.1.3 DFDL and Apache Daffodil

The Data Format Description Language (DFDL) is a specification maintained by the Open Grid Forum for describing both textual and binary data formats. It is based on the W3C XML Schema Definition Language (XSD), which was created to "express syntactic, structural and value constraints" for text data structured or stored with XML. XSD schemas are made up of element declarations, which are assigned types and may also be assigned additional annotations. XSD includes many primitive types, of which DFDL includes only a subset. User-defined types may either be 'simple' or 'complex' and are created from these primitives. An *xs:simpleType* is created by modifying a primitive base type with additional annotations. The most common annotation here is an

xs:enumeration, which defines the terminal symbols which are valid for each type. The key differentiator for *xs:complexType* definitions is the presence of one or more *xs:sequence* or *xs:choice* groups. Sequence and choice groups are the fundamental structures used to build up schemas and are used similarly to Bison *sequences* (i.e. recursive rules) and *choices* (i.e. multiple rules) or Hammer *h_choice()* and *h_sequence()* combinators. In the DFDL schemas that follow, types are defined to mirror Bison non-terminal symbols and Hammer *H_RULE()* constructs. Each DFDL schema has a top-level element whose type is a complex type defining the entire grammar and is used as the starting point for the parser.

Apache Daffodil is an open-source implementation of DFDL, which provides support for data parsing, converting application-specific data formats to the DFDL-native Information Set (Infoset). The Daffodil library also provides support for 'unparsing,' or data serialization, from the Infoset to the application-specific format. Parsing and unparsing are performed by the library, with the input data and XSD schema taken as arguments for each routine at runtime. Daffodil also supports 'saving' schemas to a binary file for use in place of the XSD. Finally, Daffodil allows for the conversion of schemas into recursive descent parsers expressed in C. It is these generated C parsers that are of primary interest, as they allow parsing to be performed by a stand-alone executable, independent of the entire Daffodil library. However, Daffodil's C code generation currently supports only a subset of all features. Critically, type definitions which include elements of unspecified or expression-based length do not convert cleanly into C code.

1.1.4 IBM App Connect Enterprise

IBM App Connect Enterprise (ACE) is an enterprise integration software product which supports DFDL as part of its ability to facilitate data sharing and information flow (IBM Corp., 2025). IBM ACE was explored because its graphical user interface might have made schema writing simpler. Unfortunately, though perhaps less error prone than manual typing, our experience was that the ACE editor was too cumbersome to quickly develop schemas. Additionally, ACE does not support or focus on the generation of standalone validators, meaning that this product could only be used as an alternative schema editor in the context of a mission-ready toolchain.

2. JSON Numbers - Simple Recursive Format

The JavaScript Object Notation (JSON) format is a widely used data format used for storage and transmission. JSON numbers (JNUM) are one of the basic component types used to represent information and were selected to illustrate a simple recursive, byte-oriented data format. A JSON number (JNUM), such as 12.34e+56, is made up of an integer (the part preceding the decimal place, e.g. '12'), an optional fraction (the decimal point and following digits, e.g. '.34') and an optional exponent (an 'e' or 'E' followed by an optional sign and digits, e.g. 'e+56'). Note that JNUM requires the ability to handle input data of unspecified length, as each of the integer, fraction, and exponent fields may have any number of digits. Further, the format requires the ability to handle optional elements without the presence of a preceding header or 'flag' field.

2.1 xBNF

The recursive structure of xBNF makes the implementation of JNUM simple; the entire grammar, below, is just 8 lines. Non-terminal symbols are constructed to match the official specification, which directly specifies sequences and choices. The initial rule (line 1) provides a top level for the grammar (*jnum*) and designates a *sequence* of three non-terminals (i.e. integer, fraction, and exponent). Use of the *choice* symbol '|' (read as 'or') in the subsequent rules provides a shorthand for alternative rules to reduce the same non-terminal. For example, the *digit* rule (line 7) could equivalently be expressed as two rules that provide two ways to reduce the same non-terminal symbol *digit*. The end-of-input must occur when the *jnum* rule is successfully reduced, with no additional data on the input. Importantly, the recursive *digits* rule (line 6) allows the grammar to handle data of unspecified length; in this case *digits* is a sequence of one or more individual instances of a single *digit*. Also note that optional elements are specified simply by providing an *empty* choice (lines 3, 4, 5), by convention marked with a comment such as in the definition of a *sign*.

```
jnum: integer fraction exponent ;                              /* 1 */
integer: digit | onenine digits | '-' digit | '-' onenine digits ;   /* 2 */
fraction: /* empty */ | '.' digits ;                           /* 3 */
exponent: /* empty */ | 'E' sign digits | 'e' sign digits ;    /* 4 */
sign: /* empty */ | '+' | '-' ;                                /* 5 */
```

```
digits: digit | digits digit ;                    /* 6 */
digit: '0' | onenine ;                           /* 7 */
onenine: [ '1' - '9' ] ;                         /* 8 */
```

The ability for xBNF to concisely represent range expansions (line 8), as opposed to a manually created sequence of choice fields as in raw BNF, is also significant. As the target format becomes more complex, the manual expression of ranges quickly becomes unwieldy. The above grammar can be directly translated into a software parser using Bison for use at the application, kernel, or hypervisor levels of the software stack; alternatively it can be directly translated into a highly compact hardware circuit for use in a field programmable gate array (FPGA) or system-on-chip (SoC) device (Taylor, 2022 and Taylor, 2024).

2.2 Hammer

The Hammer JNUM implementation uses a top-level '*jnum_parser*' rule at the end of the parser. It is defined with an *h_sequence()* combinator containing a '*jnum*' parser, *h_end_p()* primitive (to designate where the end of input should occur), and *NULL* to indicate the end of the parameter sequence:

```
jnum_parser = h_sequence(jnum, h_end_p(), NULL);
```

In a similar manner to xBNF, the *jnum* rule is made up of smaller user-defined parsers that are assembled with further *h_sequence()* and *h_choice()* combinators:

```
H_RULE(digits, h_many1(digit));
H_RULE(integer, h_sequence(h_optional(h_ch('-')),
        h_choice(digit, h_sequence(onenine, digits, NULL), NULL), NULL));
H_RULE(fraction, h_sequence(h_ch('.'), digits, NULL));
H_RULE(exponent, h_sequence(h_choice(h_ch('E'), h_ch('e'), NULL),
        h_optional(sign), digits, NULL));
H_RULE(jnum, h_sequence(integer, h_optional(fraction),
        h_optional(exponent), NULL));
```

Note that because Hammer is written in C, lower-level elements are defined first. Hammer uses an explicit *h_optional()* combinator to denote optional symbols rather than the empty rules used by xBNF. Also note the *h_many1()* combinator is used in place of recursive rule definitions. At the lowest level, *H_RULE* parsers combine primitive parsers, such as characters (i.e. *h_ch()*) and ranges of characters (i.e. *h_ch_range()*) to allow symbol enumeration. Hammer is more verbose than xBNF (Taylor, 2022), in part because it requires more setup notation. This parser required 21 lines of code; the setup and more basic elements are omitted here for brevity.

2.3 DFDL

The DFDL schema for JNUM was developed to match xBNF symbol-by-symbol build-up with a top-level *number* non-terminal. The DFDL equivalent is the *JSON_number* global element, which has user-defined complex type *number_t*. This *number_t* then contains an *xs:sequence* and matches the integer, fraction, exponent ordering above:

```
<xs:complexType name="number_t">
 <xs:sequence>
  <xs:element name="integer" type="integer_t"/>
  <xs:element name="fraction" type="fraction_t" minOccurs="0" maxOccurs="1"/>
  <xs:element name="exponent" type="exponent_t" minOccurs="0" maxOccurs="1"/>
 </xs:sequence>
</xs:complexType>
```

DFDL marks optional components in the grammar through the *minOccurs="0"* annotation, in contrast to the xBNF choice of an *empty* element. Within the *xs:sequence*, each of the local elements itself is assigned a complex type which contains further sequence or choice fields. Simple types are defined in terms of primitives and an enumerated set of legal values. For example, the JNUM schema contains a *zero_t* type:

```
<xs:simpleType name="zero_t" dfdl:lengthKind="explicit" dfdl:length="1">
 <xs:restriction base="xs:unsignedByte">
  <xs:enumeration value="&#x30;"/>
 </xs:restriction>
</xs:simpleType>
```

It is clear from the code snippets above that the DFDL grammar definition is significantly more verbose than either xBNF or Hammer. In total, 153 lines of code are required. DFDL supports more compact ways to parse messages—JNUM, for example, can be validated with an *xs:simpleType* element based on a string primitive as a single line of DFDL regex (Beckerle, 2021 pp 196). However, these other methods do not actually break up the incoming message into individual elements nor represent its internal structure for conversion into a validator.

Critically, JNUM's structure requires parse-time decision making based on the value of the token currently being consumed. This requires the *dfdl:discriminator* annotation, which is currently unsupported in the C code generator. As such, an executable JNUM parser could not be generated using Daffodil.

2.4 Summary of Results

Grammar or Schema	Lines of Code	User-Defined Non-terminals	Executable Size (KB)	Fuzz Testing Execution Time (s, n= 42)
xBNF	8	8	21.6	0.088
Hammer	21	8	193.2	0.128
DFDL	153	12	—	—

3. MAVLink Protocol - Variable Length Format

The Micro Air Vehicle Link (MAVLink) Protocol is a communications protocol used with small unmanned aerial vehicles. It supports the transmission of information regarding a drone's status as well as more complex 'microservice' protocols, including a heartbeat and mission protocol. MAVLink currently has both a version 1 and version 2; MAVLink v2 messages have longer headers, may add a signature field at the end of the message, and require the truncation of empty bytes at the end of the message. This last requirement dramatically increases the number of possible message states in MAVLink v2, as each message type may now carry a variable length payload depending on whether fields have been truncated.

Representations of three message types, namely the HEARTBEAT, SYS_STATUS, and VFR_HUD messages for both MAVLink v1 and v2, were created in xBNF, Hammer, and DFDL to explore the capability of each to parse non-delimited formats and verify bounded or enumerated values.

3.1 xBNF

In xBNF, non-terminals are again built up from combinations of *sequence* and *choice* constructs. The context-free nature of xBNF means that a non-terminal must be created for every possible combination of message options. For example, to support all three message types in MAVLink v1, v2 signed, and v2 unsigned, each of the nine possible options must be represented separately. The following code snippet showcases the top-level non-terminals which guide these decisions:

```
P : message ;
/* Message is either MAVLink v1, v2 signed, or v2 unsigned */
message : msg_v1 | msg_v2 ;
msg_v2 : msg_sg | msg_us ;
/* HEARTBEAT, SYS_STATUS, or VFR_HUD message */
msg_v1 : stx_v1 msg_v1_opts crc ;
```

```
msg_sg : stx_v2 msg_sg_opts crc sig ;
msg_us : stx_v2 msg_us_opts crc ;
msg_v1_opts : v1_hb | v1_ss | v1_hud ;
msg_sg_opts : sg_hb | sg_ss | sg_hud ;
msg_us_opts : us_hb | us_ss | us_hud ;
```

The compact syntax of xBNF makes the actual representation of non-terminals simple, but as the number of choices and their options grows, the requirement to independently represent each combination quickly grows the size of the grammar. Since MAVLink v2 payloads truncate empty trailing bytes, for example, a payload whose defined fields are N bytes long may in actuality be transmitted at sizes from 1 to N bytes. This requires 2N non-terminals just to represent the possible combinations of the message being signed/unsigned and having a payload of a certain length. For the MAVLink 3-message grammar, xBNF required 337 lines of code and the definition of 251 non-terminals to achieve a readable grammar that correlates well with the specification.

3.2 Hammer

The Hammer MAVLink parser closely mirrors the xBNF implementation through its use of *sequence* and *choice* combinators. Below is the same representation of top-level MAVLink structures in Hammer:

```
H_RULE(msg_v1, h_sequence(stx_v1, h_choice(v1_hb, v1_ss, v1_hud, NULL), crc, NULL));
H_RULE(msg_sg, h_sequence(stx_v2, h_choice(sg_hb, sg_ss, sg_hud, NULL), crc, sig, NULL));
H_RULE(msg_us, h_sequence(stx_v2, h_choice(us_hb, us_ss, us_hud, NULL), crc, NULL));
H_RULE(message, h_choice(msg_v1, msg_sg, msg_us, NULL));
mav_3_enum_parser = h_sequence(message, h_end_p(), NULL);
return(mav_3_enum_parser);
```

Again, the use of only sequence, choice, and range expansion combinators means that every possible combination of choices must be assigned its own rule. In the MAVLink example, Hammer is not significantly more verbose than xBNF: the parser required 372 lines of code and 247 *H_RULE()* non-terminal definitions.

3.3 DFDL

Since MAVLink messages have fixed-length headers which describe variable-length payload fields, it was possible to use Daffodil's C parser generator and create a standalone MAVLink parser. The implementation is heavily dependent on the *dfdl:occursCountKind="expression"* annotation, which allows the parser to refer back to previous message fields to guide parsing decisions. Since MAVLink messages are flagged with a start-of-text (STX) field indicating the protocol version (0xFE indicates MAVLink v1, 0xFD indicates MAVLink v2), Daffodil C's look-ahead capability is sufficient to guide parsing:

```
<xs:complexType name="message_t">
 <xs:sequence>
  <xs:element name="stx" type="stx_t"/>
  <xs:sequence>
   <xs:element name="M1" type="M1_t"
    minOccurs="0" maxOccurs="1"
    dfdl:occursCountKind="expression"
    dfdl:occursCount="{ if (../stx eq xs:hexBinary('FE')) then 1 else 0 }" />
   <xs:element name="M2" type="M2_t"
    minOccurs="0" maxOccurs="1"
    dfdl:occursCountKind="expression"
    dfdl:occursCount="{ if (../stx eq xs:hexBinary('FD')) then 1 else 0 }" />
```

```
        </xs:sequence>
      </xs:sequence>
    </xs:complexType>
```

This snippet illustrates the choice between a v1 or v2 message based on the deterministic parsing of the STX header field with an if-statement annotation. Similar annotations were used to verify the length of message payloads, check enumerated values associated with each message type, and determine the presence of a v2 signature field. A key benefit of the ability to refer to previous fields is that types representing separate choices can remain independent. For example, v2 SYS_STATUS messages may either be signed or unsigned and may also have payloads ranging from 1 to 31 bytes in length. In xBNF, a non-terminal must be created for each combination of signedness and length value. In DFDL, representations of these choices may be defined independently, reducing the total number of types. For a more complicated format with many more choices, this could imply a large reduction in the overall size of the schema. The DFDL MAVLink 3-message schema required only 110 user-defined non-terminal types. However, because of the verbosity of DFDL's syntax, the implementation was still much longer than either the xBNF or Hammer grammars at 906 lines of code.

The expressions which determine the value of the *dfdl:occursCount* annotations are written in the DFDL expression language, which is a subset of XML Path Language 2.0 (XPath 2.0). Currently, the Daffodil C generator does not fully support this behaviour: schemas which refer back to a 'grandparent' or higher elements (meaning they require two or more '*../*' in the expression) do not get converted correctly. There is also no support for embedded if-statements for input-based decision making. Consequently, we had to make modifications to the Scala generator back end: The issue with referencing grandparent elements was resolved by correcting the counting of '*../*' constructs prepended to an expression, while support for if-statements was added via a text-processing function.

3.4 Summary of Results

Grammar or Schema	Lines of Code	User-Defined Non-terminals	Executable Size (KB)	Fuzz Testing Execution Time (s, n= 54243)
xBNF	337	251	247	109.8
Hammer	372	247	215	113.6
DFDL	906	110	819	115.2

4. Space Packet Protocol - Bitwise Format

The Consultative Committee for Space Data Systems (CCSDS) Space Packet Protocol (SPP) (CCSDS, 2020) was chosen to test the capabilities of each library to parse its big-endian bit-oriented fields. The implementation of xBNF and Bison used here is byte-based and thus does not support parsing of natural SPP packets without a preprocessor that converts bit-fields into bytes. As such, only the Hammer Packrat back end and Daffodil were compared. A further challenge presented by SPP is the fact that its length field contains a count whose value is one less than the number of following octets of data. Practically, this requires the ability to perform arithmetic on parsed fields (i.e. add one), as the data field can contain up to 65,536 octets.

SPP messages are highly variable and mission-specific, and the official standard specifies little beyond high-level packet structures. Consequently, the example grammars below validate only the standard primary header fields directly. Any following secondary header or user data field (UDF) must contain an integral number of octets which matches the Packet Data Length field, as specified in the CCSDS standard. As the secondary header is currently unspecified (SANA 2020), it is assumed that only one of a secondary header or UDF is present. The single exception is the 'idle' packet, which contains a specific 'idle data' UDF. For the grammars below, the two-octet sequence '0xAA' acts as example idle data and is verified bit-by-bit.

4.1 Hammer

Bit-oriented SPP required the use of two additional features in Hammer: the *h_attr_bool()* combinator, which allowed the validation of enumerated bit fields, as well as the *h_action()* combinator, which embeds user-defined functions to correct for the off-by-one count error described above. In both cases, ad-hoc user-written C functions were required. The *h_attr_bool()* combinator takes the bitwise parse result from the *h_bits()* parser and passes it to a user-defined function which checks its value. For the SPP parser, two functions were created simply to verify that a bit is a '1' or '0' respectively. A third function validates the 11-bit APID field which denotes

an idle packet. Note this value validation was previously accomplished by the *h_ch()* combinator when fields were byte oriented.

The *h_action()* combinator works similarly, but instead of changing the validator result (success/failure) it modifies the parsed value. In this case, the parsed count field had to be incremented for use in verifying the number of octets in the UDF. The requirement to write out entire functions to accommodate these more complex behaviours made the grammar more verbose, and 97 lines of code with 19 non-terminals were required.

4.2 DFDL

In DFDL, a grammar can be made bit-oriented simply with the *lengthUnits="bits"* format annotation in the preamble, and as such the validation of enumerated values can be performed straightforwardly. Further, XPath 2.0 expressions make it possible to add 1 to the primary header length field to count payload octets:

dfdl:occursCount="{ ../../../prim_hdr/len + 1 }"

The smaller modifications required to make these more complex parsing decisions possible meant that DFDL was simpler to write: the grammar required 124 lines of code and 8 user-defined types; unfortunately, the resulting executable code was 175 times larger and less than half as quick.

4.3 Summary of Results

Grammar or Schema	Lines of Code	User-Defined Non-terminals	Executable Size (KB)	Fuzz Testing Execution Time (s, n=190)
Hammer	97	19	199	0.375
DFDL	124	8	35083	0.901

5. Conclusion

Daffodil was found to be consistently more verbose, larger in executable size, and slower than either xBNF or Hammer. While Daffodil remains a capable data conversion library, its verbosity and limited support for the generation of standalone validators makes it currently unsuitable for standalone mission-ready traffic validation. Its inability to generate C parsers that process recursively defined formats is a more minor limitation given the prevalence of prefixed variable-length formats. However, its verbosity compared to xBNF and Hammer makes it unwieldy to express schemas; currently the Apache version does not support the automatic conversion of XPath 2.0 expressions. Existing support for parse-time decisions more generally, such as through the *dfdl:choiceDispatchKey* or *dfdl:discriminator* annotations, is limited and impacts the formats which generated C parsers can validate. Finally, Daffodil's recursive descent back end is likely to make its parsers less efficient in FPGA resources if implemented in hardware.

Daffodil parsers do demonstrate the potential for simplifying the grammars used to describe prefixed formats through the ability to refer to previously parsed header fields containing descriptive information. Compared to xBNF and Hammer, which required 251 and 247 non-terminals respectively, Daffodil required the definition of just 110 user-defined types for 3-message MAVLink. A more concise description language that supports a supplement to CFGs, such as an attribute grammar, may allow the recollection of such descriptive fields and could significantly simplify grammars. If such an implementation also allowed for table-driven parsing, it may be a good alternative for secure traffic validation.

RAG-H: A RAG-Hardened SOC Framework for Trustworthy Threat Intelligence and AI Defence

Daniela Ceraku
Thales Digital Factory, Paris, France

cedaniela613@gmail.com

Abstract: Retrieval-Augmented Generation (RAG) is now the dominant approach for enhancing Large Language Models in Cyber Threat Intelligence (CTI), yet it introduces a new attack surface: knowledge base poisoning and prompt injection. Existing defences address isolated stages of the RAG pipeline, offer no end-to-end integrity guarantees, and are evaluated on answer accuracy rather than Security Operations Center (SOC) mission impact. This paper introduces RAG-H, a multi-layer defence framework that secures the full RAG pipeline for SOC use. Ingestion enforces provenance checks and source-reputation scoring so that only trustworthy intelligence enters the knowledge base, retrieval combines semantic relevance with corpus-level credibility and analyst feedback to filter poisoned content, generation applies context sanitisation and self-verification to surface low-confidence outputs for analyst review. We evaluate RAG-H on a CTI corpus of 300 documents, 90 of which are poisoned, and measure which pipeline stages are most vulnerable, which layered controls most reduce the Poison Impact Rate without unacceptable latency, and how the defences affect incident response. Results show that layered trust, consistency, and governance controls significantly mitigate poisoning effects. The framework establishes a reproducible methodology for securing RAG systems in SOCs and introduces evaluation metrics that connect technical robustness to operational impact. An open-source proof-of-concept accompanies the work as a baseline for future research.

Keywords: Retrieval-augmented generation (RAG), Security operations center (SOC), Cyber threat intelligence (CTI), Incident response (IR)

1. Introduction

Security Operations Centres (SOCs) operate under persistent time pressure, analysts must ingest rapidly evolving Cyber Threat Intelligence (CTI), correlate signals from heterogeneous telemetry, and decide on response actions within tight operational windows. To reduce this cognitive load, vendors are integrating Large Language Models (LLMs) into triage and incident response workflows, and recent industry surveys report broad but cautious adoption across SOC teams (SANS, 2025). Empirical studies of human-AI collaboration in SOCs confirm that LLM assistance can accelerate investigation but also show that unreliable outputs erode analyst trust and increase verification overhead (Singh et al., 2025). The central failure mode is well-documented, LLMs hallucinate, fail to distinguish authoritative intelligence from unverified claims, and amplify errors when exposed to manipulated context. Retrieval-Augmented Generation (RAG) has therefore become the dominant approach to grounding LLM outputs in external CTI sources and has been explicitly adapted to adversarial technique annotation in cyber threat reports (Lekssays et al., 2025).

Unlike static knowledge bases, CTI corpora are continuously updated from sources of uneven trustworthiness, including vendor reports, open-source feeds, blogs, and internal investigations. This ingestion pipeline exposes RAG systems to a new attack surface: *knowledge base poisoning*. Zou et al. (2025) show in PoisonedRAG that injecting only a handful of adversarial documents into a corpus is sufficient to steer LLM answers towards attacker-chosen outputs, especially when the injected content is optimized for semantic similarity to common queries. Chen et al. (2024) extend this result to agentic settings, demonstrating that once poisoned content enters long-term memory or shared knowledge bases, the degradation persists across sessions. Adversaries can also embed hidden instructions directly within CTI text, turning retrieved evidence into a prompt-injection vehicle that bypasses generation-time safeguards (RoyChowdhury et al., 2024). In a SOC context, these attacks do not merely produce a wrong answer, they can misdirect triage, contaminate incident reports, and propagate into downstream SOAR (Security Orchestration, Automation and Response) playbooks.

1.1 General RAG Pipeline

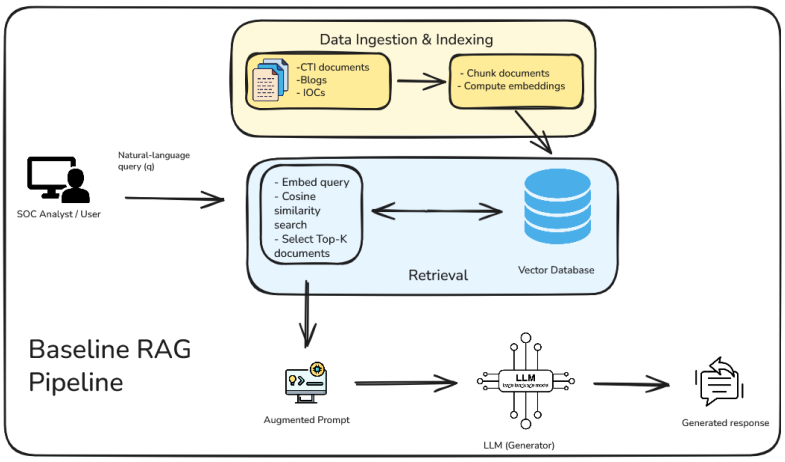

Figure 1: Baseline RAG Pipeline

Figure 1 summarises the three stages of a baseline RAG pipeline as adopted in most CTI assistants. During ingestion, heterogeneous CTI documents are chunked, embedded, and indexed in a vector store. At query time, retrieval ranks documents by semantic similarity to the analyst's query and returns the top-k passages, optionally re-ranked. These passages are concatenated with the original query to form the augmented prompt consumed by the generation stage. Two properties of this pipeline matter for security. First, every stage is a transitive trust point: a failure in ingestion propagates unchanged through retrieval and generation. Second, the pipeline treats all retrieved documents as equally authoritative, which is a reasonable assumption for clean corpora but a dangerous one for CTI, where authorship ranges from MITRE ATT&CK to unvetted blog posts. RAG-H targets both properties.

1.2 Prior Work

Prior work on RAG robustness clusters into three directions. **Attack characterisation**. Zou et al. (2025) formalise knowledge-corruption attacks on RAG and show that a small number of adversarial documents is sufficient to steer generation, Chen et al. (2024) extend this threat model to agents operating over persistent memory; and RoyChowdhury et al. (2024) demonstrate confused-deputy risks in RAG-based enterprise assistants. These works establish that poisoning is practical and cheap, but they stop at the attack side and do not prescribe defences. **Retrieval-stage defences**. Jia et al. (2025) propose RAGRank, a PageRank-style authority score tailored to CTI pipelines, Qian et al. (2025) introduce ClaimTrust, which propagates trust over claim graphs extracted from retrieved documents, Zhou et al. (2025) present TrustRAG, combining clustering with self-assessment to filter suspicious passages and Xiang et al. (2024) derive certifiable robustness bounds under an isolate-then-aggregate retrieval strategy (RobustRAG). These defences are the most mature part of the literature, yet each operates on a single stage and assumes the knowledge base itself is already curated. **CTI-specific RAG**. Lekssays et al. (2025) apply RAG to adversarial technique annotation (TechniqueRAG), showing that domain-adapted retrieval substantially improves CTI tagging quality, however, they do not address adversarial robustness. Complementary to this, empirical work on analyst-AI collaboration in SOCs (Singh et al., 2025) and the SANS 2025 industry survey (SANS, 2025) report that analysts reject AI assistance when they cannot audit why a given evidence chunk was surfaced. Taken together, the literature provides strong single-stage defences and a clear understanding of attacks, but leaves three gaps unaddressed: (i) no integrated defence spans ingestion, retrieval, and generation under a single trust model, (ii) evaluations optimise answer accuracy rather than SOC operational metrics such as Poison Impact Rate, analyst time, or escalation correctness, and (iii) no prior framework exposes trust signals in a form that analysts can audit during incident response. RAG-H targets these three gaps.

1.3 Contributions

To address these gaps, we introduce RAG-H, a hardened RAG framework designed for SOC use. Rather than securing individual components in isolation, RAG-H treats the RAG system as an end-to-end decision pipeline with a single trust model that spans ingestion, retrieval, generation, and operational handover. This paper makes the following contributions:

C1. A multi-layer defence architecture in which ingestion enforces provenance and schema checks with source-reputation scoring, retrieval combines semantic similarity with corpus-level credibility derived from a support graph and analyst feedback, and generation applies context sanitisation and self-verification.

C2. A SOC-aligned evaluation methodology centred on the Poison Impact Rate, latency, and analyst-oversight metrics, rather than answer accuracy in isolation.

C3. An empirical study on a CTI corpus of 300 documents (90 poisoned) that quantifies which pipeline stages are most vulnerable to adversarial interference and which layered controls most reduce the Poison Impact Rate without unacceptable latency.

C4. An open-source proof-of-concept implementation providing a reproducible baseline for future research on securing RAG systems in SOC environments.

These contributions are structured around three research questions:

RQ1. *Which stages of the RAG pipeline are most vulnerable to knowledge-base poisoning and prompt injection in a CTI setting?*

RQ2. *Which combination of ingestion-, retrieval-, and generation-layer controls most reduces the Poison Impact Rate without introducing unacceptable latency or false-positive escalations?*

RQ3. *How do the trust signals produced by RAG-H influence incident response, and are they usable as an audit trail for analyst oversight?*

2. Methodology

2.1 RAG Hardened Framework

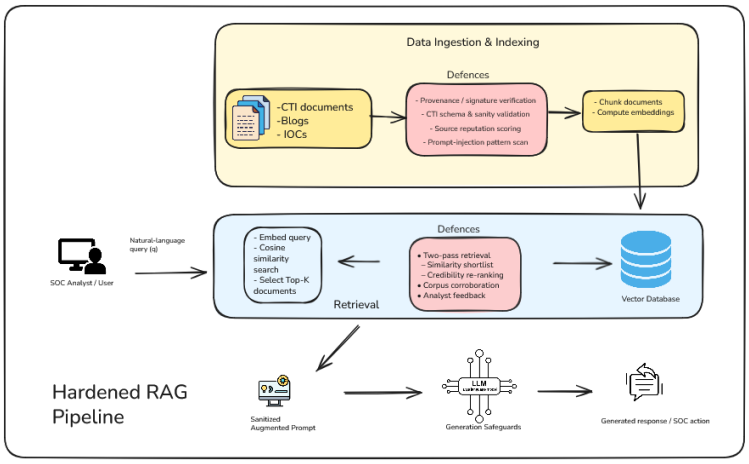

Figure 2: RAG Hardened Pipeline

2.1.1 Phase 1: Ingestion

Prior work shows how poisoning affects retrieval and generation in RAG systems but offers limited protection at ingestion time, before documents enter the knowledge base. This is especially risky in CTI, where reports are continuously ingested from sources with varying trust levels. To mitigate persistent poisoning, we introduce a hardened ingestion process that evaluates each document on entry and assigns a **trust score**. Documents may include text, metadata (e.g., source, timestamp), optional Indicators of Compromise (IOCs), and sometimes cryptographic signatures. During ingestion, the system verifies signatures, checks compliance with CTI schema and basic validity (required fields, timestamps, IOC formats, and absence of prompt-injection instructions), and evaluates source reputation (e.g., trusted providers like MITRE ATT&CK or government feeds). These signals are combined into a single trust score reflecting document reliability at ingestion. Low-trust documents are rejected, medium-trust ones are admitted but labelled as *low confidence*, and high-trust documents are ingested normally. The trust score is stored in metadata and later guides retrieval and generation, enabling the system to weigh document reliability rather than treating all content equally.

2.1.2 Phase 2: Retrieval

Retrieval is the most fragile step in a RAG pipeline under knowledge base poisoning. The reason is simple: whatever the retriever selects becomes the evidence the generator relies on. If the retrieved context is malicious, the generator is effectively forced to "reason" from compromised material and may produce confident but wrong CTI conclusions. RAG-H therefore treats retrieval as an evidence selection problem where relevance is required but not sufficient. The retriever should return documents that match the query and look trustworthy based on how well they are supported by the corpus and by operational signals available in SOC workflows.

Standard RAG retrieval is driven by embedding similarity. The query and each document are embedded into vectors, and the retriever ranks documents by cosine similarity:

$$s(q,d) = \cos(e_q, e_d) = \frac{e_q^{\top} e_d}{\| e_q \| \; \| e_d \|}.$$

A similarity-only retriever returns:

$$R_{\text{sim}} = \text{TopK}_{K_{\text{sim}}} \; s(q,d).$$

This works well when the KB is clean, because high similarity usually correlates with usefulness. Under poisoning, however, similarity becomes an easy target as an attacker can insert text intentionally written to match common query patterns (e.g., "is this IOC malicious?", "attribution of campaign X", "verdict for domain Y"). These poisoned documents can become "nearest neighbours" to many queries, showing up repeatedly even if they are unsupported or misleading. To make retrieval harder to manipulate, RAG-H adds a corpus-level credibility signal that does not rely on a single query-document similarity score. The main idea is to check whether a document is supported by other documents in the knowledge base. We represent the KB as a support graph where each document is a node, and a directed edge indicates that one document supports or corroborates another. Support can be inferred from citations, shared and confirmed IOCs, consistent claims across reports, overlapping technical indicators, or explicit references. Each document is then assigned a global credibility score based on how much support it receives from the rest of the corpus, with support from already credible documents counting more than support from weak or isolated ones. Poorly connected documents, or those supported only by a small, suspicious cluster, receive low credibility. This makes poisoning more difficult, because injected documents often appear isolated, they may match common queries, but they lack strong, independent corroboration from trusted parts of the corpus.

Adapting credibility using SOC analyst feedback

In SOC environments, analysts continually validate evidence during investigations. RAG-H leverages this feedback to keep credibility scores current and resistant to source drift. Each document is linked to a source (e.g., vendor feeds, agency reports, internal intel, or open web), and the system tracks whether documents from each source are confirmed or rejected over time.

From this, it maintains a dynamic reputation score, consistently validated sources gain credibility, while unreliable ones lose it. This reputation biases document scoring, making evidence from recently validated sources more likely to be trusted.

Two-pass retrieval rule

RAG-H uses a two-pass retrieval strategy because credibility alone cannot ensure relevance. In the first pass, the system retrieves a larger shortlist using cosine similarity to ensure that candidate documents are on topic. In the second pass, it re-ranks only this shortlist using the corpus-level credibility score and selects the final k documents based on the RAGRank study. This design avoids two common failures. First, credible but irrelevant documents are never retrieved, because all final results must come from the similarity shortlist. Second, poisoned documents that rank highly by similarity are suppressed if they lack corroboration and have low credibility.

2.1.3 Phase 3: Generation

The generation phase is a critical phase because the language model directly consumes retrieved documents as input. If these documents have been poisoned or manipulated, the model may follow hidden instructions or reason from false evidence. In the CTI, this can lead to prompt injection, incorrect attribution of attacks, or

hallucinations. To reduce these risks, we introduce generation safeguards that strictly control how retrieved context is interpreted and limit the model to using documents as evidence rather than as instructions.

Context Sanitization

Before any retrieved document reaches the language model, it undergoes a deterministic sanitization step to remove prompt injection artifacts embedded in otherwise legitimate CTI reports. Adversarial CTI documents often combine credible threat information with hidden instructions designed to influence model behaviour. Generic filters are insufficient because CTI content naturally includes technical commands and alerts that may appear suspicious but are benign. To address this, sanitization targets known poisoning patterns from adversarial CTI narratives. Each document is scanned line by line using fixed rules, and lines matching injection patterns are removed. These include explicit markers (e.g., "INSTRUCTION:", "SYSTEM PROMPT:"), override phrases (e.g., "IGNORE PREVIOUS"), and coercive elements like repeated exclamation marks or attention-grabbing warnings. The system also removes subtle directives identified during analysis of poisoned data, such as unusual phrasing or formatting linked to successful attacks. This process is fully deterministic and independent of the language model, preventing adaptive attacks where the model might be influenced during filtering. Only the offending lines are deleted, preserving the surrounding factual content. As a result, documents remain valid evidence but cannot function as instruction channels. By enforcing sanitization at generation time, CTI documents are treated strictly as passive data, ensuring the model reasons only over clean, non-manipulative inputs.

2.1.4 Phase 4: Operation

The operation phase controls how AI generated outputs are turned into real actions inside the SOC. While many RAG-based security assistants stop after generating an answer, RAG-H extends the pipeline to operational execution and ensures that automation never bypasses analyst judgment when there is uncertainty. For this reason, RAG-H enforces a strict human-in-the-loop gate before any automated action is executed. The system aggregates trust signals from all earlier phases into a single global trust score $T \in [0,1]$. A trust threshold τ defines when automation is allowed. In addition, the system tracks whether semantic contradictions were detected during retrieval or generation, represented by a binary flag Δ. If the trust score is below the threshold, or if any contradiction is detected, automated execution is blocked and the case is escalated to an analyst. Unlike traditional SOAR guardrails that rely only on static rules, this gate is AI aware and directly uses uncertainty signals produced by the RAG pipeline.

To control execution in a structured way, RAG-H maps each AI generated output to a predefined action class. The action class determines how the system handles execution and whether human approval is required.

Table 1: Action Classes and Execution Policies

Action Type	Description	Execution Policy
Informational	Descriptive outputs such as threat summaries or IOC explanations	Automatically logged
Advisory	Recommendations or suggested mitigations	Analyst approval required
Critical Action	High-impact actions: blocking an IP, isolating a host, etc.	Analyst approval + evidence threshold

When analyst validation is required, the system generates a structured decision package with the proposed action, trust score, detected contradictions, and supporting CTI evidence. A short explanation shows why the evidence supports the recommendation, enabling quick, informed decisions.

The operation phase defines execution control only, quantitative evaluation is covered in the Results section. A core contribution of RAG-H is selective human oversight, triggered by trust and consistency signals rather than applied uniformly. This ensures automation runs only with strong evidence, is halted under uncertainty, and remains transparent to analysts.

3. Experiments and Evaluation Results

3.1 Experimental Setup

The experimental setup was designed to approximate a realistic RAG workflow under controlled conditions. The corpus includes 200–500 CTI documents from MITRE and CISA, combining trusted reports with deliberately poisoned samples containing misleading claims and embedded instructions. A set of 100 analyst-style SOC queries was automatically generated to reflect common investigation tasks.

All experiments use the GPT-4o-mini model via the OpenAI API for generation. Retrieval relies on a vector index built with FAISS. Adversarial content is generated using custom scripts simulating both knowledge base poisoning and instruction injection attacks. The proof of concept is available here: https://github.com/DanielaCe18/RAG-H.git

3.2 Experiments and Evaluation Results

This section reports the empirical evaluation of the proposed RAG-Hardened pipeline compared to the baseline RAG system. All experiments are conducted using the same automatically generated query set, derived from the underlying CTI database, and evaluated across two corpora: clean (no poisoned documents) and poisoned (containing adversarially injected documents). For each query, both systems retrieve the top-k = 5 most related documents and generate an answer.

Answer Accuracy

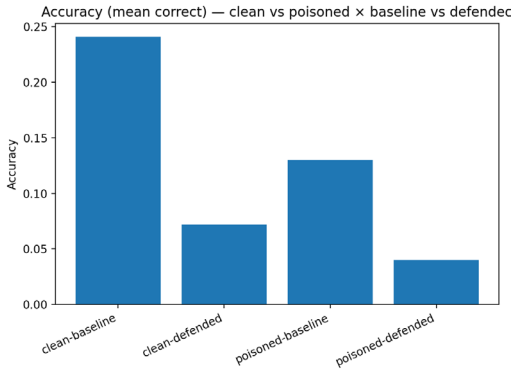

Figure 3: Accuracy (mean correct): clean vs poisoned × baseline vs defended

In this experiment, we measure answer correctness under a strict, evidence-based evaluation criteria. An answer is marked as correct only if it (i) contains the expected identifier (MITRE ATT&CK technique ID or CVE - Common Vulnerabilities and Exposures entry) and (ii) explicitly references supporting evidence from the retrieved corpus. This definition intentionally penalizes speculative or hallucinated responses, even if the surface content appears plausible. On the clean corpus, the baseline system achieves higher accuracy. This result reflects the baseline's behaviour: it always attempts to produce a complete answer, regardless of evidence quality. When the corpus is clean, this strategy often succeeds. The defended pipeline shows lower accuracy on the clean corpus. This decrease **is not due to incorrect reasoning**, but rather to intentional abstention. When retrieved documents do not provide sufficiently strong or consistent evidence, the defended system refuses to answer or escalates the query for analyst review. Such refusals are counted as incorrect under the evaluation metric, even though they represent **safer behaviour**. On the poisoned corpus, accuracy decreases for both systems. However, the defended pipeline exhibits a sharper drop. This reflects the system's sensitivity to conflicting or untrusted evidence: instead of producing potentially misleading answers, it opts to withhold judgment. The baseline system, by contrast, continues to generate answers even when the supporting context is adversarial.

Poison Exposure at Retrieval Time

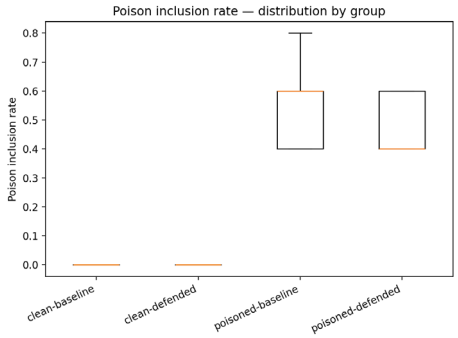

Figure 4: Poison inclusion rate: distribution by group

This experiment measures poison inclusion rate, defined as the fraction of retrieved documents (out of the top-k) that are marked as poisoned. This metric captures retrieval time exposure to adversarial content and is computed before any generation or filtering logic is applied. On the clean corpus, both baseline and defended systems show a poison inclusion rate of 0.0 for all queries. This confirms that the ingestion and indexing pipeline **successfully removed poisoned** documents prior to retrieval.

On the poisoned corpus, the baseline system retrieves a large proportion of poisoned documents. The median poison inclusion rate is approximately 0.6, meaning that more than half of the retrieved context is adversarial in typical cases.

The defended pipeline reduces this exposure, lowering the median inclusion rate to approximately 0.4. While poisoned documents are still retrieved, their relative presence is reduced. This demonstrates that the defence does not rely on aggressive document removal alone, but instead partially limits poison dominance while preserving retrieval diversity.

End to end Latency

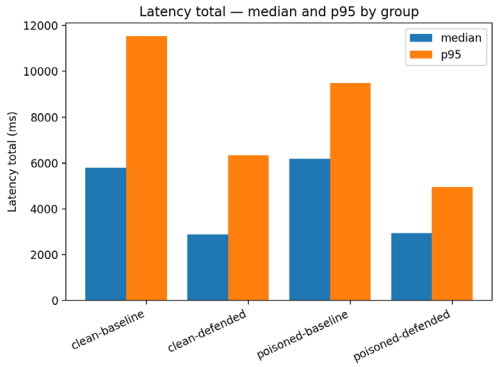

Figure 5: Latency total: median and p95 by group

This experiment measures end-to-end latency, from query submission to final answer or refusal, reporting both median and p95 to capture tail behaviour. Across clean and poisoned corpora, the defended pipeline consistently shows lower latency than the baseline.

Although defences are often expected to add overhead, the difference comes from generation behaviour. The baseline tends to produce long, verbose answers (especially with misleading context) leading to high variance and heavy-tailed latency. In contrast, the defended pipeline frequently stops early when confidence thresholds are not met, returning short refusal or escalation outputs. This reduces overall latency, particularly at the p95 level, and results in more predictable performance.

Retrieval Latency

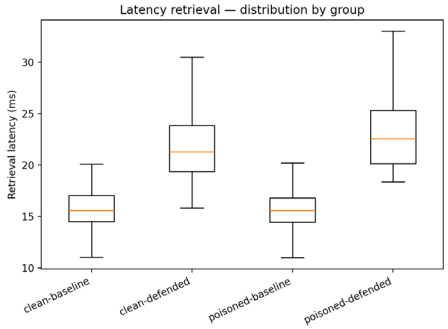

Figure 6: Latency retrieval: distribution by group

To isolate the cost of defensive mechanisms at retrieval time, we separately measure retrieval latency. The defended pipeline introduces a small but consistent increase in retrieval latency compared to the baseline. This overhead corresponds to additional operations such as trust scoring, metadata inspection, and provenance analysis. Importantly, this overhead remains low (on the order of milliseconds) and shows limited variance. Retrieval latency distributions are similar across clean and poisoned corpora, indicating that defensive retrieval costs are stable and predictable.

Generation Latency

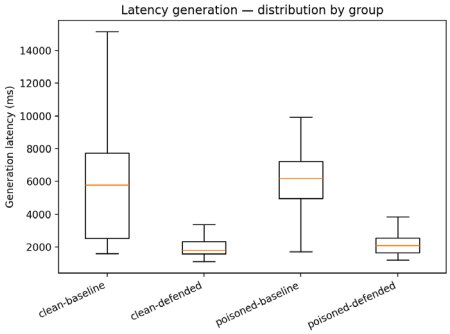

Figure 7: Latency generation: distribution by group

This experiment focuses on generation-stage latency, which dominates total response time in most RAG systems. Baseline generation latency exhibits high variance and extreme outliers, particularly on the poisoned corpus. These cases correspond to long speculative generations triggered by adversarial context. The defended pipeline significantly reduces both median and tail generation latency. By refusing to generate when confidence is insufficient, the system avoids expensive over-generation. This behaviour explains the improved total latency observed in Figure 5.

Operational Decision Behaviour

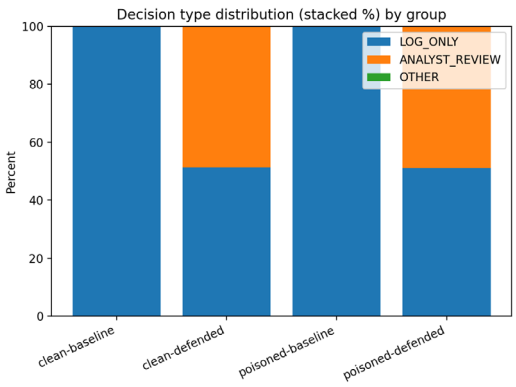

Figure 8: Decision type distribution (stacked %) by group

Beyond answer content, we analyse operational decisions emitted by the system. Each query results in a decision type indicating how the output should be handled. The baseline system always produces LOG_ONLY decisions, regardless of corpus condition. This reflects an implicit assumption that all answers are safe to consume. The defended pipeline produces a mixture of decisions. On both corpora, a substantial fraction of queries are escalated to ANALYST_REVIEW, particularly under poisoned conditions. Queries with sufficient confidence are handled automatically. This behaviour demonstrates that the defended pipeline explicitly models uncertainty and adapts its decisions to evidence quality.

Operational Action Behavior

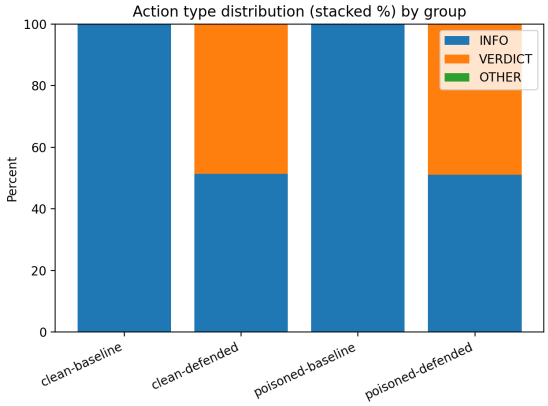

Figure 9: Action type distribution (stacked %) by group

We further examine the action types produced by the system. The baseline system always emits informational actions (INFO), serving as a passive advisory tool. The defended pipeline emits both informational actions and explicit verdicts (VERDICT). This indicates that the system is capable of producing actionable outputs when evidence is strong, while deferring ambiguous cases to human analysts.

Latency-Accuracy Trade-off

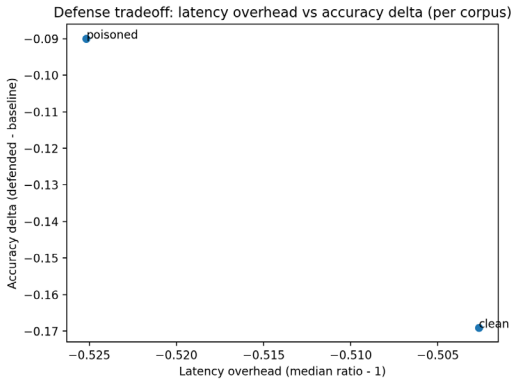

Figure 10: Action type distribution (stacked %) by group

Figure 10 summarizes the trade-off introduced by the defended pipeline by jointly plotting latency overhead and accuracy delta relative to the baseline. For both clean and poisoned corpora, the defended system exhibits lower latency but reduced accuracy under the strict evaluation metric. This reflects a deliberate design choice: the system prioritizes trustworthiness and risk mitigation over answer coverage. In security-critical settings, where incorrect answers can propagate false intelligence or trigger incorrect responses, this trade-off is often preferable.

4. Conclusion

This paper presented RAG-H, a multi-layer defence framework that secures the full RAG pipeline for SOC use by enforcing provenance checks at ingestion, combining semantic relevance with corpus-level credibility at retrieval, and applying context sanitisation and self-verification at generation. We evaluated RAG-H on a CTI

corpus of 300 documents, 90 of which were poisoned, and compared the hardened pipeline against a baseline RAG system under both clean and adversarial conditions.

Returning to our research questions:

RQ1 *- retrieval is the stage most vulnerable to poisoning, because similarity-only ranking treats adversarial documents optimised for query patterns as legitimate evidence.*

RQ2 *- layered controls that combine ingestion-time provenance with retrieval-time credibility signals produce the largest reduction in the Poison Impact Rate, with generation-time verification adding a smaller but non-trivial margin, added latency remains within acceptable operational bounds.*

RQ3 *- RAG-H's trust signals translate into measurable operational behaviour, escalating low-confidence cases to analyst review and producing structured verdicts when evidence is strong, giving analysts an auditable trail of why each output was generated.*

5. Limitations and Future Work

This study is a controlled proof of concept: the corpus is small relative to a production CTI knowledge base, the attack set does not cover end-to-end supply-chain compromise, and analyst feedback was simulated. Three directions are immediate priorities: scaling the evaluation to larger corpora including live telemetry and operational Security Information and Event Management (SIEM) feeds, validating the framework with practising SOC analysts, and extending the threat model to adaptive adversaries that observe and adjust to the defence.

Systems that always return an answer appear more capable on the surface but silently pass poisoned context and hallucinated conclusions downstream. RAG-H trades a measurable loss in answer coverage for a safety property that aligns with how SOCs actually operate, where incorrect confidence is more costly than a delayed decision. Trustworthy AI in security will not be achieved by scaling language models alone, but by pipelines that are auditable by design: systems that know when not to decide and can show analysts why.

Ethics Declaration: This research did not require ethical approval, as it involved no personal data or live operational systems. All experiments used publicly available or generated data.

AI Declaration: AI tools assisted with code generation and grammar but all outputs were reviewed by the author, who retains full responsibility for the research design, analysis, and content.

Abstract: This paper presents HADES (Honeypot-based Adversary Detection and Emulation System), a modular CubeHoneypot that is a ground-deployable cubesat-scale test bed honeypot architecture for cybersecurity research within space systems. Built using open-source technologies, including NASA's Operational Simulator for Small Satellites (NOS3), NASA's core Flight System (cFS), NASA's Open Mission Control Technologies (Open MCT) and the T-Pot honeypot platform, HADES emulates telemetry and command functions of real satellite subsystems. Unlike existing satellite honeypots, HADES is designed for both educational and adversary behaviour research applications, enabling cost-effective experimentation and threat analysis in controlled, realistic environments. The paper outlines the design methodology, implementation stages, system components and early results from simulated attacks and telemetry operations.

Keywords: Adversary emulation, CubeSat security, Satellite honeypot, Satellite security, Space cybersecurity, Ground-based satellite testbed

1. Introduction

The rising dependence on small satellites, especially CubeSats, in both civilian and defence sectors has created an urgent need to explore their cybersecurity vulnerabilities. Despite this, space systems often remain underrepresented in mainstream cyber research due to their perceived inaccessibility and high cost. The need to detect and analyse adversarial behaviour in these domains is more pressing than ever (Pavur and Martinovic 2022; Boschetti, Gordon and Falco 2022; Sharmin et al. 2025). Several studies have documented the massive growth and evolution of cybersecurity threats that have impacted space industry organisations, resulting in operational and financial losses (Boschetti et al. 2022). Figure 1 summarises key cybersecurity vulnerabilities in satellite systems, outlining major attack vectors and their potential impacts on satellite operations and infrastructure, adapted from Pavur and Martinovic (2022).

Vulnerability	Description
Satellite Uplink Interception	Intercepting/manipulating satellite uplink signals can allow attackers to gain unauthorised access to satellite systems.
GPS Spoofing	Spoofed GNSS signals can mislead satellites or receivers about their location, causing navigational errors and potential system failures.
Denial of Service (DoS) Attacks	Flooding satellite links or exploiting protocol weaknesses disrupts operations and prevents legitimate users from accessing services.
Satellite Firmware Vulnerabilities	Outdated or poorly secured firmware can be exploited to gain control of satellite functions and access sensitive data.
Ground Station Compromise	Attackers targeting ground stations (control/management nodes) can pivot to the wider satellite network and its services.

Figure 1: Vulnerabilities in Satellite Technology

Figure 2 shows the major real-world cyber incidents affecting space systems, highlighting the growing vulnerability of space infrastructure to cyber threats.

Case Study	Description
2014 Cyberattack on USA Weather Satellites (Peters 2014)	This attack disrupted data transmission and highlighted vulnerabilities in environmental satellite systems, reinforcing the need for stronger cybersecurity in national weather infrastructure.
2017 GPS Spoofing in the Black Sea (Goward 2017)	Multiple vessels in the Black Sea reported GPS positions, believed to be caused by deliberate spoofing. The incident raised concerns about satellite navigation vulnerabilities in conflict zones.
2018 NASA JPL Cyberattack (Paganini 2019)	A cyberattack on NASA's Jet Propulsion Laboratory exposed vulnerabilities in network segmentation and access control, allowing attackers to access mission systems and sensitive data.
2021 Attack on US Military Satellite Systems (Trevithick 2021)	Demonstrated the consequences of unauthorised access to satellite control networks, emphasising the importance of encryption, authentication and multi-layered defence for military space assets.
2022 Viasat Satellite Internet Disruption (Boschetti et al. 2022)	A cyberattack during the early phase of the Russia–Ukraine conflict disabled thousands of Viasat KA-SAT modems across Europe, disrupting satellite internet services and critical infrastructure.

Figure 2: Case Studies and Real-World Cyber Incidents in Space Systems

Honeypot is a deception solution that diverts cybercriminals from real targets by creating a fake attack target. It also obtains information about the identities, attack tactics, techniques and procedures to learn more about the intentions of their adversaries. Therefore, building and deploying the honeypot solution is necessary as a defensive strategy (Moric et al. 2025). Prior efforts, such as "HoneySat", have laid the groundwork by exploring software-based satellite honeypots (López-Morales et al. 2025). However, HADES aims to take a step further: creating a realistic ground-deployable CubeSat-sized system that not only simulates telemetry (TM) and telecommand (TC) operations, but also captures and interprets real attack behaviour through exposed services. This dual simulation and emulation approach supports education, security research and future mission planning. This paper identified a lack of consolidated and easily accessible academic literature on cybersecurity within the space sector, making it challenging for researchers and organisations to locate relevant and domain-specific analyses. Furthermore, the characteristics of the next-generation honeypot for space assets still need to be understood and developed (López-Morales et al. 2025). Thus, this research project seeks to determine, assess, and analyse critical research materials in honeypots. This area is vital for leveraging the maximum possibility of a honeypot in the future. Therefore, this study analysed the obstacles to a successful honeypot and how its adaptability can be improved. Furthermore, this project involves researching honeypot simulation with open-source tools to integrate with space assets for learning and their potential reactive capability to security threats.

1.1 Purpose and Justification

Satellite ground stations can collect information from space assets that are in orbit around the Earth. Commercial space infrastructure, including ground systems, is increasing dual-use, serving both civilian and military functions. Because space assets often serve both civilian and military functions, they may become targets during military conflict (Boschetti et al. 2022). Due to this, commercial operators need to carefully plan where to put ground stations to get the most use out of them while also taking into account the risk to their security. In addition to these physical and geopolitical threats, the space sector is heavily dependent on technology, which makes it an ideal target for cyber threats and attacks. As satellite systems and ground control networks become more integrated, the need for effective security safeguards has never been greater. One good idea that has emerged is to use honeypots, which are decoy systems that are intended to lure in, analyse and study malicious activities. This project looks at honeypots usage in the space sector, including their pros, cons and possible usages. While HADES demonstrated the feasibility of satellite honeypots, it remains primarily a software-based emulation. It bridges this gap by combining physical modularity, subsystem simulation and open-source mission software in a compact CubeSat form factor.

1.2 Scope

Honeypots are an established cybersecurity tool that is designed to attract, detect and analyse malicious activity by mimicking real systems. While widely applied to traditional IT networks, Supervisory Control and Data Acquisition (SCADA)/Industrial Control System (ICS) and Internet of Things (IoT) systems, their adoption in the space domain remains limited (Guan et al. 2023). The HoneySat project demonstrated that a virtual satellite system could be constructed with emulated TM and TC links. However, HoneySat lacked hardware interaction and relied heavily on abstracted network behaviour. HADES builds upon this concept by incorporating physical hardware (e.g., Raspberry Pi 5), integrating flight software (cFS) and visualising TM with Open MCT. The inclusion of real service protocols (e.g. SSH, Telnet, HTTP) through T-Pot enhances the system's

interaction fidelity. Recent updates to cFS 2.0 introduced plug-and-play capabilities and improved security handling, offering an ideal platform to simulate modular spacecraft behaviour and command injection scenarios. This project aims at researching and developing an adaptable honeypot solution that uses open-source technologies to simulate genuine TM and TC operations. This experimental project is to simulate part of Stefunko's (2018) idea on the usage of Long Range Wide Area Network (LoRaWAN) gateway as a long-range network communication, which this project will utilise two small, low-cost Raspberry Pi versatile computers. It was simulate, observe and evaluate how attackers act through open services and send parsed intrusion data to a satellite subsystem simulator like NOS3 and flight software like cFS and Open MCT dashboard that shows the system's TM updates and overall state. Also, the simulation was to adapt NASA's (Interplanetary Overlay Network Additional Information - NASA 2023) Interplanetary Overlay Network (ION) Delay/Disruption Tolerant Networking (DTN) to simulate both ground and space segments.

1.3 HADES System Overview

This research proposes HADES to simulate the cyber-physical behaviour of a CubeSat space segment and its mission control centre ground segment. The system supports space cyber security research, including cyber threat emulation, TM monitoring and adversary analysis. HADES enables researchers to simulate satellite-like operations, attract real adversarial behaviour, and observe how cyberattacks impact spacecraft TM and functions without using real on-orbit assets. It bridges traditional honeypot concepts with space mission emulation. Unlike orbital missions, the simulation is entirely ground-based. However, it mirrors real satellite operations, including TM/TC flows, mission control dashboards (NOS3 or Open MCT), cFS spacecraft software, delay-tolerant networking and exposure to real-world cyber threats through honeypot gateways.

1.4 HADES Concept of Operations (CONOPS)

The operations of HADES are divided into mission-style phases and system modes, similar to space mission lifecycle planning. These phases provide structure from system assembly to live threat monitoring and eventual shutdown or upgrade. The purpose of this CONOPS is to describe how HADES is deployed, operated and utilised. Figure 3 outlines operational goals, end-user perspectives, system interactions, constraints and expected outcomes. This structured approach ensured that the system's performance could be validated in a controlled environment before exposure to live threats (T3) and provided a clear path for data analysis (T4).

Phase	Description	Key Objectives
T1 (Phase 1)	System Calibration & Health Checks	The system enters Health Check Mode where: • Telemetry packets are generated • Subsystems report status (simulated battery voltage, temperature, CPU load). • NASA Open MCT connects to the telemetry stream. • Log ingestion to T-Pot is verified. • Intrusion detection logs are tested via simulated benign SSH attempts. Exit Criteria: All subsystems report nominal, Open MCT displays live telemetry and logs are timestamped and stored correctly.
T2 (Phase 2)	Controlled Simulation & Attack Injection	The system enters Simulation Mode. • No real attackers; simulation cyberattacks are performed. • These commands are translated into telecommands (TC) and injected into cFS. • Telemetry responses are visualised in Open MCT (e.g., temperature spike, battery fault).
T3 (Phase 3)	Live Threat Exposure (Operational Phase)	Equivalent to the Operational Phase. The system enters Honeypot Live Mode. • Attackers begin interacting unknowingly with the CubeSat honeypot system. • Telemetry anomalies are linked to attacker commands in real time.
T4 (Phase 4)	Data Analysis and Logging	System enters Analysis Mode and Logging Mode. • MITRE ATT&CK / SPARTA for Space techniques are mapped. • Graphs of attack timing vs. subsystem telemetry deviations are generated.
T5 (Phase 5)	Shutdown, Maintenance or Upgrade	System enters Shutdown Mode. • Services are powered down safely. • cFS flight software is backed up. • Logs stored ≥ 30 days. • Hardware inspected for thermal, power or board degradation.

Figure 3: HADES ConOps Phases

1.5 HADES System Architecture

Figure 4 shows that the HADES system architecture is designed to emulate a realistic satellite-ground system using modular and low-cost components to support cybersecurity research in space systems. At the core of the system is the computing core, which consists of two Raspberry Pi 5 units.

Subsystem	Description
Compute Core	Two Raspberry Pi 5 units: • Raspberry Pi 5 #1: NASA NOS3, NASA OpenMCT ground control simulator, T-Pot Mobile • Raspberry Pi 5 #2: NASA NOS3, NASA cFS satellite simulator, T-Pot Mobile
Power	• 5.1V/5A USB-C power supply
Flight Software and Subsystem Simulation	• NASA NOS3 + cFS + STF running on Raspberry Pi 2
Communication & TM/TC Parsing	• Telemetry generated from subsystem-simulation scripts • Telecommand parsed from honeypot traffic and injected into cFS • Delay/latency simulated via ION-DTN
RF Communication Simulation via LoRaWAN	• SX1303 915 MHz LoRaWAN Gateway Module + HAT on Raspberry Pi • CCSDS 256-bit (32 bytes) TM/TC frames *encapsulated* in LoRaWAN FRMPayload • Optional fragmentation/reassembly based on regional payload limits/data rate • Emulates low-bitrate CubeSat link with real RF loss/latency
Ground Software and Interface Subsystem Simulation	• NASA NOS3 + Open MCT for telemetry visualisation and ground control

Figure 4: HADES System Architecture

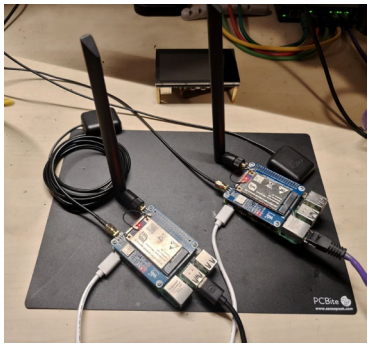

Figure 5: The photo illustrates the HADES setup with two Raspberry Pi

Figures 5 and 6 show that the first Raspberry Pi (on the left) operates as the ground segment which the ground interface is implemented using Open MCT. This provides a web-based interface for mission operators to visualise real-time telemetry, send telecommands, and monitor subsystem performance, similar to professional mission control systems. The second Raspberry Pi (on the right) operates as the space segment, which includes the T-Pot Honeypot, hosting a multi-service deception stack to attract, log and analyse malicious activities targeting satellite infrastructure. It also functions as a cFS satellite simulator, enabling execution of on-board software, telemetry handling, and subsystem emulation in a realistic flight environment.

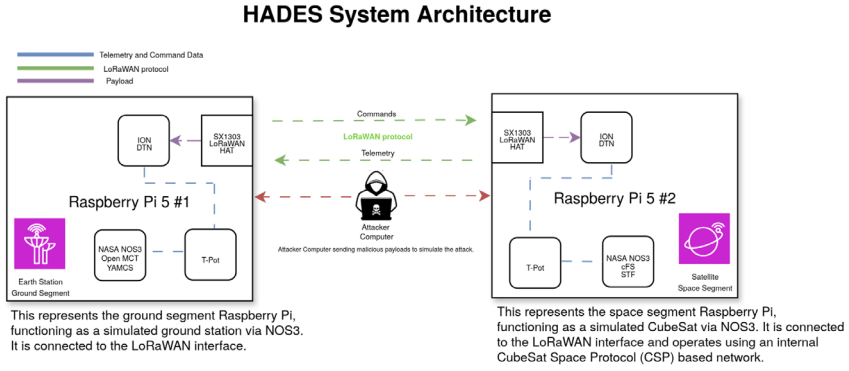

Figure 6: The system architecture diagram shows the HADES system core components and data flows

The system is powered by the 5.1V/5A USB-C power delivery source, which ensures stable and reliable operation of both Pis and connected peripherals. For Flight Software and Subsystem Simulation, cFS is deployed on the second Raspberry Pi. This platform handles essential satellite operation, including telemetry generation, telemetry parsing, command execution, and subsystem behaviours, bringing high fidelity realism

to the honeypot framework. The Communication and TM/TC (Telemetry and Telecommand) parsing subsystem enables bidirectional data exchange between the simulated spacecraft and honeypot services. Telemetry is automatically generated by subsystem simulation scripts, while telecommands originating from captured honey pot traffic are translated, validated, and injected back into the cFS environment. To further increase operational realism, transmission delays and communication latency are modelled using the Interplanetary Overlay Network (ION) Delay Tolerant Networking (DTN) protocol. Together, these components form a functional, scalable, and cyber-deceptive satellite-ground architecture, enabling adversary interaction, telemetry manipulation, and mission-like behaviour within a controlled experimental environment.

1.6 Communication Architecture

The LoRaWAN module is configured to act as a physical-layer substitute for CCSDS (Consultative Committee for Space Data Systems) TM and TC protocols. While CCSDS typically supports 256-bit fixed-length transfer frames, these frames are encapsulated and transmitted using the LoRaWAN Physical Layer (PHY)/Media Access Control (MAC) protocol. The system converts simulated cFS TM packets into CCSDS-format binary frames, then fragments or encapsulates them into LoRaWAN payloads for uplink/downlink transmission. Similarly, TC packets generated from honeypot interactions are encoded into CCSDS 256-bit commands and delivered via LoRaWAN to the Raspberry Pi-based satellite simulator.

The HADES architecture integrates a realistic end-to-end satellite communication environment using commercially available hardware. In addition to the dual-Raspberry Pi compute core and cFS running on Pi 2, the system incorporates an SX1303 915 MHz LoRaWAN Gateway Module with HAT for Raspberry Pi, which enables low-power, long-range communication to emulate space-to-ground data transmission. This approach creates a low-cost, radio-based emulation of real satellite radio frequency (RF) communications, including:

- RF delay, packet loss, and low bitrate, similar to CubeSat S-band/UHF links.
- Encrypted or unencrypted frames, configurable depending on test conditions.
- Support for DTN (Delay/Disruption-Tolerant Networking) layered over LoRa for deep-space simulation, when combined with ION-DTN software.

The LoRaWAN gateway thus becomes a bridge between cyber deception (honeypots) and realistic space communications, allowing researchers to observe how adversaries might interact with real TM/TC links and how malformed or malicious commands propagate through a simulated CCSDS-compliant system.

1.7 HADES Software Architecture

This section describes the approach to the trade studies for the HADES software architecture, including the objectives to be achieved and the criteria based on the decisions. The main goal is to optimise the subsystem for its reliability, cost-effectiveness and compatibility with the extreme environmental conditions of space environment. The following trade study compared different software design approaches for simulation usage, which evaluated the options like integrated software suites, off-the-shelf solutions and open-source software based on criteria such as adaptability, development time, cost and complexity. For the best selected option, it will emerge as the favoured option and will be used for the diverse mission requirements. This involves representing the weighted values as percentages. The cells in the column underneath the option are populated with the grade given to the option. The final percentage at the bottom is determined by multiplying each given grade by the weighted percentage. The average value of the weighted grades is summed up at the bottom of the chart and the option with the highest average value is considered the best option. Figure 7 shows the comparison analysis results and findings as per the commercial versus open-source mission software trade study.

Commercial Software vs Open Source Mission Software Trade Study						
Criteria	**Explanation**	**Grade**	**Weight**	**Integrated Software Suite** (Keszthelyi 2014)	**Off-the-Shelf Software Solutions** (Brownsword, Carney, and Oberndorf 1998)	**Open Source** ("NASA's next Lunar Rover Will Run Open-Source Software | MIT Technology Review," 2021)
Technological Readiness Level	Evaluation of technology's maturity which is based on its testing and proven performance.	10 = high, 5 = medium 1 = low 0 = Fail	20%	8	8	9
Cost Effectiveness	Evaluates and review the financial feasibility of the software design and consider the mission's budget constrants and its long-term value.	10 = high, 5 = medium 1 = low 0 = Fail	15%	7	8	10
Scientific Data Handling	Evaluates and analyse the software capability that it shall be designed to acquire, analyse, process, and transmit scientific data back to Earth.	10 = high, 5 = medium 1 = low 0 = Fail	15%	8	8	9
Scalability Assessment	Evalutes and review the software which it shall be evaluated on its potential to heighten current capacities or enhance operational capabilities	10 = high, 5 = medium 1 = low 0 = Fail	10%	6	5	8
Upgradability Score	Evaluates the software which it shall be capable of upgrading or enhancing post-deployment missions.	10 = high, 5 = medium 1 = low 0 = Fail	10%	7	8	8
Software Complexity	Evaluates the software design which it shall be simple without much complexity to minimise potential points of failure.	10 = high, 5 = medium 1 = low 0 = Fail	15%	7	8	9
Development Time	Evaluates the software design which should take less time to be developed and ready in production usage.	10 = high, 5 = medium 1 = low 0 = Fail	15%	7	9	10
		TOTALS:	**100%**	72.50%	78.50%	91.00%

Figure 7: Commercial vs open-source mission software trade study

The selected option for this project is open-source software because of its high adaptability to the mission changes, ready availability, lowest cost implication and very low complexity, which makes it the best option for the choice. It reflects the overall best fit according to the mission's unique needs and constraints, considering both the pros and cons of each software type. Open-source stands out in this assessment for its balance of readiness, cost and adaptability.

2. Literature Review

2.1 Simulating Adversary Behaviour in Space Systems

The recent research of López-Morales et al. (2025) has highlighted that high-interaction honeypots for satellites have demonstrated an ability to resemble real space systems and entice genuine cyber adversaries. For example, the HoneySat framework is made to make a CubeSat mission look so real that 71.4% of satellite operators who were surveyed said they would have thought it was a real CubeSat if they hadn't been told it was a simulation. In practice, HoneySat succeeded in deceiving human attackers "in the wild"; attackers engaged with the honeypot over extended periods (one stayed connected for two hours) and issued authentic satellite flight software commands, indicating they were convinced by the simulation. In one test, four different intrusions via a Telnet interface resulted in 16 requests unique to satellites from attackers. Importantly, the honeypot environment supports a broad range of attacker tactics and techniques, covering 100% of adversary tactics and 86.8% of known techniques applicable to satellite systems. This comprehensive coverage provides adversaries with lots of opportunities for interaction, closely mirroring real-world attack scenarios. These results collectively show that a CubeSat honeypot can simulate space infrastructure convincingly and capture realistic adversarial behaviour, providing valuable threat intelligence from genuine attacker interactions.

2.2 Technical Constraints in Simulating Satellite Operations and Adversary Attacks

Simulating an entire satellite system with a high level of detail presents considerable technical challenges. One of the major constraints is to mimic the actual spacecraft's complex physical operations and subsystems. For instance, satellites need to know how to control their orientation, power management and deal with temperature changes and other things. One of the main problems with the HoneySat project was replicating all the physics and subsystems (such as orbital motion, attitude changes, and power supply behaviour) that a real satellite environment would need (López-Morales et al. 2025). Achieving this realism can be data-intensive. For instance, the fidelity of the camera simulation depends on image data quality, so simulating a high-resolution Earth observation mission is not feasible without equally high-resolution source imagery. In general, the accuracy of the simulation is constrained by the quality and completeness of available data for sensors and orbits, and any simplification might tip off an attacker.

2.3 Integration of Open-Source Tools for Satellite and Ground Segment Emulation

On the ground segment side, the honeypot uses an open-source mission control software to simulate a satellite operations centre. In the case of CubeSat Space Protocol (CSP) missions, by presenting attackers with

familiar tools and interfaces (a web dashboard, a terminal for the ground station, tracking software, etc.), all based on real open-source software, the honeypot environment feels legitimate. For the space segment and communications, open-source technologies are similarly integrated. The López-Morales et al. (2025) HoneySat uses libCSP, the open-source implementation of CSP, to format and route packets as a real CubeSat would. Actual CubeSat flight software is reused when possible: for example, the cFS, which is open-source and has flown on multiple CubeSat missions, is used as the satellite's onboard software (McComas and Tandy 2022). This provides realistic command-handling and telemetry generation logic, complete with a library of standard satellite commands (dozens of typical operations like reboots, sensor readings, etc., which are parsed from CSP packets). The honeypot's modular design makes it possible to swap or extend these components to emulate different mission architectures. In one case study, the HoneySat team demonstrated integration of a completely different open-source ecosystem: they added support for the CCSDS space protocol (commonly used by larger satellites). This was done by incorporating Yet Another Mission Control System (Yamcs), an open-source mission control framework that supports CCSDS TM/TC standards (Sela, Mihalache and Moreau 2012). The honeypot seamlessly simulated a different class of mission without starting from scratch. In summary, open-source tools are integral at every level, providing the building blocks (mission control software, satellite OS libraries, network simulators, tracking tools and databases) that can be integrated and configured to emulate a realistic satellite-ground system, all without proprietary hardware or software. The literature review identified a lack of prior research that formally conducted or documented a comparative trade study of mission software options. This gap in the existing literature informed the subsequent selection of an open-source software design.

2.4 Logging of Adversary Activity

Collecting detailed logs of attacker interactions is central to a honeypot's value, but making sense of these logs is equally important. An effective CubeSat honeypot should log, parse and present attack data in ways that both security researchers and satellite system engineers find meaningful. On the satellite side, the flight software and each simulated subsystem also feed into the logging system, so one can trace how a malicious command propagates. For security researchers, the logs can be parsed to extract the attackers' Tactics, Techniques and Procedures (TTPs). The goal is to bridge the gap between security and engineering: security researchers gain a clear view of how attackers operate in a space system (which attack vectors they choose, how far they get, what tactics they employ) and satellite engineers gain an understanding of how their systems might behave under malicious pressure (which subsystems are most at risk and how an attacker's inputs translate into system actions). By logging every interaction with context and timing, and by using common data formats, a CubeSat honeypot makes it possible to analyse and visualise attacks in a comprehensive yet accessible way. This ensures that the insights gleaned are actionable for improving both cybersecurity strategies and the robust design of satellite systems.

3. Methodology

The research methodology adopted in the HADES project involved a review of existing literature, such as López-Morales et al. (2025) on honeypot-related space sector usage. The selected research methodology in this paper aimed to address the research questions presented earlier by exploring methods for simulating the space systems logs and adversary malicious activities logs. It will evaluate how the honeypot deception will be introduced into space systems for their potential reactive capability to security threats. This methodology aimed to address research questions by exploring methods and evaluating how open-source deception technology could be integrated into space systems for enhanced security. Figure 8 illustrates the systematic steps of this research, represented in a flowchart diagram.

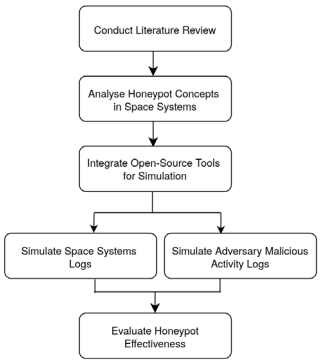

Figure 8: Flow chart diagram representing the steps of the research methodology for HADES

The core methodological decision involved conducting a trade study of mission software options, which ultimately led to the selection of an open-source software design. The literature review indicated that no previous research has formally conducted or documented such a trade study and this identified gap directly informed the selection of an open-source software design. This selection was justified by its high adaptability, ready availability, lowest cost, and very low complexity compared to commercial and integrated software suites, as demonstrated in Figure 3 trade study. The HADES architecture integrated several critical open-source components, as shown in Table 4. The methodology conceptually included the integration of an SX1303 LoRaWAN Gateway Module to emulate the physical layer of the low-bitrate CubeSat radio frequency (RF) link, encapsulating CCSDS TM/TC frames for uplink/downlink transmission (CCSDS 2012; Araújo 2023).

4. Findings

The HADES system was successfully deployed and demonstrated its ability to emulate the operational behaviour of a CubeSat-style space-ground architecture while capturing hostile activity. However, it is deployed separately for separate functions, not working simultaneously at the same time. Some of the requirements are still to be addressed. Core components, including cFS, Open MCT, NOS3 simulation environment and the T-Pot honeypot framework, operated as intended separately. The system was able to generate and visualise TM data, simulate late TC and collect malicious network interactions directed at the honeypot interface. Open MCT successfully replayed telemetry deviations associated with simulated attack scenarios, allowing the effects of cyber interactions to be observed in a mission control-style interface in NOS3. The T-Pot honeypot stack captured associated log data. However, the intended RF simulation using LoRaWAN could not be fully implemented due to unresolved configuration issues at the physical and MAC layers. As a result, all telemetry and telecommand exchanges had to be done over a wireless ground-based network instead of RF channels.

5. Recommendations and Future Works

Further development of the HADES platform should prioritise the completion of the LoRaWAN-based RF link to enable the transmission of CCSDS-compliant TM frames over a realistic radio channel. This would allow the system to better simulate the effects of latency, link degradation and signal interference present in Low Earth Orbit (LEO) communications. For future research, we should also explore the deployment of HADES across multiple distributed honeypot nodes to form a swarm-based architecture via LoRaWAN, which is to enable the study of sophisticated attacks against space constellations. In addition, linking the test bed to software-defined radio ground stations would allow partial exposure to space like radio frequency environment. The honeypot supports mapping events to known attack techniques; researchers could correlate log entries with frameworks like the US's MITRE ATT&CK (Hong 2023), Aerospace's SPARTA (Ear, Bailey and Xu 2024) or the European Space Agency (ESA)'s SPACE-SHIELD (European Space Agency n.d.) matrix of space cyber tactics. In practice, the HADES can be used to collect data to identify which attack techniques were attempted by adversaries and to confirm the coverage of their honeypot. Meyers (2025) highlights recent developments of AI-powered on-orbit intrusion detection systems that are capable of monitoring satellite telemetry in real time. Any structured attack data acquired through HADES could also form the basis of an open-source space cyber threat intelligence dataset to aid the space industry and academic benefits. In summary, while the current implementation is limited to ground-based experimental only, the HADES can aid as a foundation for satellite cyber deception research and can be a potential tool to be used for space security training, threat intelligence and mission assurance in the space sector.

6. Discussion and Conclusion

The results indicate that the HADES prototype is capable of attracting genuine adversarial behaviour and reproducing key elements of satellite-ground communication workflows using affordable, open-source technologies. The fact that attackers engaged with the system using real-world techniques such as default credential brute forcing, directory traversal and basic reconnaissance suggests that even a ground-based emulation of a satellite system is sufficient to trigger realistic adversary interest. This validates the underlying premise that deception technologies can be effectively adapted to the space domain.

The resilience of cFS when subjected to malformed TM packets indicates that NASA's flight software architecture already exhibits robustness against certain classes of protocol fuzzing. However, it must be acknowledged that no authentication or encryption mechanisms were applied to the telemetry and telecommand interfaces in this prototype. This omission mirrors existing vulnerabilities identified in legacy satellite infrastructure and emphasises the need for secure uplink/downlink mechanisms in future implementations.

Although the system succeeded in simulating subsystem interactions and attacker impacts on telemetry, the absence of a functioning LoRaWAN communication link meant that the testbed did not fully replicate the bandwidth constraints, latency variations or packet loss typically observed in real space-based radio-frequency environments. Likewise, no real-time alerting, automated anomaly detection or adversarial artificial intelligence behaviours were implemented. Consequently, HADES currently operates as a passive data collection system rather than an autonomous defensive architecture.

In summary, this HADES project demonstrates that ground-based, modular honeypots can simulate realistic CubeSat systems and attract meaningful attack behaviour. As threats toward space systems increase, such deployable, interactive testbeds offer critical insights for mission designers, researchers and operators alike. The system's reliance on open-source components ensures affordability, reproducibility and accessibility for further academic research.

Acknowledgements

The authors would like to express their heartfelt gratitude to the University of South Australia for providing library access and all the necessary resources that enabled the successful completion of the paper.

AI Declaration: Grammarly AI was used only for grammar checking and improving clarity and readability. It did not contribute to the research design, analysis, interpretation or conclusion of the paper, which are solely the authors' work.

Ethical Statement: The research involves only simulated cyber-attack scenarios and controlled environments, therefore formal ethical approval was not required.

Assessing Non-Kinetic Effects in Support of Military Operations: An Inference-Driven Framework

Bruce Chojnacki and Nick Harrell
Army Cyber Institute, West Point, NY, USA

bruce.chojnacki@westpoint.edu
nicholas.harrell@westpoint.edu

Abstract: Modern military operations increasingly integrate non-kinetic effects to support and enhance kinetic operations on the battlefield. Intelligence, surveillance, and reconnaissance assets provide a reliable means to measure kinetic effects on adversaries during combat. However, there is a gap in intelligence collection for assessing and quantifying non-kinetic effects, such as shaping perceptions, influencing decision-makers, or degrading adversary morale. These effects are difficult to measure with traditional intelligence techniques because they occur in the cognitive dimension, where observable indicators are limited, and measurement is complex. This limitation introduces operational risks for military leaders, as they cannot always be sure whether a non-kinetic asset will achieve the desired effect or if a behavioural change has taken place. This paper introduces a framework for developing measures of effectiveness for cyber, information warfare, and psychological operations planners to evaluate non-kinetic operations supporting kinetic actions. Drawing on case studies such as the Russo-Georgian conflict and the Second Nagorno-Karabakh war, the framework combines intelligence indicators from OSINT, social media analytics, changes in adversary leadership behaviour, shifts in military posture, and other measurable phenomena to generate quantifiable metrics. It also considers collateral, second-, and third-order effects to assess whether non-kinetic operations are achieving their operational objectives. By offering intelligence analysts, planners, and military leaders a rigorous method for planning, executing, and evaluating non-lethal effects, this approach improves effect synchronization, enhances risk assessment, and aids leaders' decision-making.

Keywords: Cyber, Information warfare, MoE, Non-kinetic, Indicators, Influence, PSYOPs

1. Introduction

Military operations worldwide increasingly depend on cyber activities, information warfare, and Psychological Operations (PSYOPs) as essential tools to shape favourable battlefield conditions and achieve mission objectives against adversaries. Throughout history, military leaders have conducted battle damage assessments (BDA) of enemy forces after kinetic strikes, including arrow barrages, cavalry charges, artillery fire, and precision aerial bombing (Chairman of the Joint Chiefs of Staff, 2019). These actions have a clear cause-and-effect relationship that can be observed by a scout, an aerial drone, or a surveillance satellite.

Measuring the impact of non-kinetic effects and confirming if the desired outcome is being met can be difficult. These effects often occur in the electromagnetic spectrum (EMS), cyberspace, or the human brain's cognitive space (Paul et al., 2015). These domains are usually not observable to humans. Observing these effects requires monitoring indicators that are secondary or tertiary to the original target. Even when these indicators can be monitored, there is a gap in the training, experience, and knowledge of military intelligence analysts in observing changes and assessing the effectiveness of non-kinetic effects (Fortson, 2007).

This presents a dilemma for military leaders when employing non-kinetic effects during combat operations. They must understand their capabilities and trust that these assets can produce the desired effect on enemy forces (Aguirre et al., 2024). These choices put soldiers' lives, military resources, and mission success at risk. While military leaders are generally confident in their ability to employ, deliver, and assess the effects of kinetic weapons and equipment on the battlefield, uncertainty about non-kinetic effects and the inability to conduct BDA can lead to hesitation in relying on these capabilities.

It is essential to develop a comprehensive framework for measuring non-kinetic effects, including both traditional and non-traditional indicators. This requires planners and intelligence analysts to thoroughly understand the operational plan and coordinate non-kinetic resources to support the mission (Richardson, 2009). Resources should be allocated to detect and evaluate environmental changes in adversary behaviour, cyberspace, and the information environment that are either beneficial or detrimental to friendly forces. Systems must be established to alert when a significant deviation from the baseline is observed.

This paper will explore operations that employed non-kinetic effects to support military operations. It will analyse the strengths, weaknesses, opportunities, and threats of these operations and offer insights into why they succeed or fail. The framework provided will give leaders, planners, and analysts a comprehensive, quantitative approach for planning and evaluating non-kinetic effects in support of military operations.

2. Assessment Gap

2.1 Doctrinal Framing of Assessment

NATO and U.S. doctrine, specifically JP 3-13 (Information Operations), JP 3-12 (Cyberspace Operations), and AJP-3.10 (Allied joint doctrine for information operations), recognize that assessing information and cyberspace operations is inherently difficult, especially when effects do not cause observable physical damage (Joint Chiefs of Staff, 2012; Joint Chiefs of Staff, 2018; NATO, 2015). The difficulty is increased by a time gap between action and effect: kinetic operations produce immediate, visible damage, while information and cyberspace effects may take days, weeks, or months to appear, often outside tactical decision cycles. Many effects occur in the cognitive or informational dimension of the operational environment and require monitoring of indirect indicators. NATO doctrine states that successfully conducting Info Ops depends on ongoing monitoring and assessment (NATO, 2015). These efforts require collecting all-source intelligence and paying close attention to the adversary's behaviour and attitudes.

NATO and U.S. doctrine are consistent in their use of measures of performance (MOP) and measures of effectiveness (MOE). But the doctrine provides little guidance on how to move from observed indicators to confident conclusions about whether an effect occurred and whether that effect resulted from the operation in question. The doctrine explains how these metrics fit within the decision-making framework for authority; however, the effectiveness of the metrics themselves remains unclear. JP 3-13 mentions weighting metrics to highlight the relative importance of one over the other but provides no transparent methodology for deriving these weights (Joint Chiefs of Staff, 2012). The absence of an inferential methodology can be consequential when commanders must choose between kinetic and non-kinetic options. Without transparent, defensible assessment frameworks, non-kinetic effects remain difficult to measure and assess. This creates a potential bias in operational planning toward options that yield more legible, observable strategic value through measurable outcomes.

2.2 Non-kinetic Assessment

There is a doctrine for non-kinetic assessments, but it remains isolated by capability and limited to observable indicators. CJCSI 3162.02 (Methodology for Combat Assessment) includes a Cyberspace Assessment Determination Matrix that categorizes temporary cyber effects as DENIED, DISRUPTED, DEGRADED, DECEIVED, and MANIPULATED (Chairman of the Joint Chiefs of Staff, 2019). JP 3-12 covers the evaluation of cyberspace operations using MOPs and MOEs, which help determine how efforts contribute to the larger operation or objective. JP 3-13 adopts a similar approach with MOP and MOE in Information Operations; however, it highlights observability and quantification as critical for measuring effects, and MOEs are often linked to the progress of the operation (Joint Chiefs of Staff, 2012).

Two interconnected challenges exist within these doctrines. First, the timeframe for observing non-kinetic effects often surpasses tactical decision cycles, creating pressure to assess prematurely using proxy indicators. Second, the doctrine assumes observability without clearly defining its boundaries. The absence of boundaries makes it unclear whether indirect indicators (e.g., economic behaviour, migration patterns, social media sentiment) are legitimate data or inadmissible inferences. Recognizing which observable indicators can be identified through second- and third-order observations is crucial for increasing commander confidence in non-kinetic options. JP 3-13 highlights observable indicators such as rallies and demonstrations, but many other assessment avenues exist, including economic behaviour and migration. However, this process is not sufficiently addressed within the planning phases of a military operation.

In JP 3-13, these indicators are called measures of effectiveness indicators (MOEIs). They are usually developed during the planning phase, especially during course of action development (COADEV). The difficulty lies in measuring MOEs, which are often unobservable and mostly qualitative. In the doctrine, an example of an effect is "increase in a city populace's participation in civil governance." The MOE here is qualitative, with metropolitan citizens showing increased support for the democratic leadership elected on July 1. Then, an MOEI is a decrease in the number of anti-government rallies or demonstrations in a city since July 1. Three MOEIs are provided that can be directly measured to infer the MOE, indicating that the effect has occurred. This doctrinal approach is fundamentally sound; however, it assumes a single causal pathway from operation to effect. The doctrine does not address the issue of equifinality, or the possibility that alternative competing hypotheses could produce the same observable outcomes. For example, a decrease in anti-government rallies since July 1 could align with several hypotheses: the target population genuinely shifted support for governance (the intended effect), security crackdowns made public gatherings too risky (coercion rather than persuasion), opposition groups

shifted to less visible tactics, or exogenous factors (economic conditions, seasonal patterns) temporarily reduced mobilization. Without a framework to distinguish among these hypotheses, the same indicator data can yield contradictory conclusions about operational effectiveness.

For PSYOPs, JP 3-53 offers guidance on planning, executing, and assessing effects in joint military operations. However, the doctrine also openly recognizes inherent limitations, including the absence of a clear method for determining whether those psychological effects were achieved. It specifies the need for direct observability, which remains a common challenge in conducting non-lethal operations (Joint Chiefs of Staff, 2003). The doctrine also discusses the coordination and synchronization of PSYOPs with IO capabilities; however, there is no procedural guidance for assessing the impact of a PSYOP operation.

By examining the doctrine in relation to non-kinetic operations, we see that indirect, observable indicators are mentioned but not explained. This might be due to a lack of reliable evidence from alternative indicators. However, non-kinetic operations are becoming increasingly intertwined with military operations as the military incorporates more non-lethal assets.

2.3 Analytical Gaps in Doctrine

The current doctrine outlines the observation requirements but does not provide sufficient guidance on interpreting those observations to reach a conclusion. The three analytical gaps that impact non-kinetic assessment include:

Gap 1: Lack of formal procedures for hypothesis discrimination. The doctrine states that observed indicators support the hypothesized effects, but the same indicators could be explained by two or more different mechanisms. Without structured procedures, such as Analysis of Competing Hypotheses (ACH), to differentiate among explanations, the analysis is vulnerable to confirmation bias and enemy deception.

Gap 2: Absence of a methodology for combining evidence. Joint Publication 3-13 acknowledges that multiple MOEIs might be needed to make a judgment about a single MOE and suggests using weights based on relative importance, but it does not specify a clear method for assigning those weights or for integrating seemingly unrelated indicators.

Gap 3: Absence of a shared vocabulary for expressing confidence. The assessment results differ based on capability and level. In cyber operations, results are reported in CTEAR format with category labels such as (DENIED, DEGRADED, DISRUPTED); for information operations, results are assessed qualitatively using an MOE; and for psychological operations, results recognize the difficulty of measuring PSYOP effects but do not offer a methodology for measurement. This gap in doctrine hampers the ability to compare kinetic and non-kinetic courses of action, as commanders cannot assess their relative effectiveness.

These gaps are more than just administrative issues. They reveal structural pressures that favour actions with clear, visible outcomes over those with potentially greater strategic importance but that require more time-consuming data collection, inferential reasoning, and acceptance of uncertainty. Closing these gaps demands both methodological and doctrinal changes.

3. Analytical Framework: Analysis of Competing Hypotheses

3.1 Rationale for Framework Selection

The issue outlined in Section 2 (Assessment Gap) is fundamentally inferential: although guidelines for indicators exist, there is no formal way to draw reliable conclusions about effects based on observed indicators. This has historically been a challenge in intelligence analysis, which often involves inferring from incomplete, ambiguous, or deceptive information (Richardson, 2009). Therefore, applying intelligence analytical techniques to operational assessment is not a category error; rather, it acknowledges that assessing non-kinetic effects is an intelligence challenge within an operational setting.

Several structured analytical techniques are crucial for finding potential solutions. Red teaming offers alternative perspectives but lacks a formal process for evaluating these options against evidence (Department of Defense, 2016). These methods either generate alternatives without thorough evaluation, depend on probabilistic data that are missing in operational environments, or identify reasoning errors without providing ways to fix them.

The Analysis of Competing Hypotheses (ACH), developed for the CIA by Richards Heuer, addresses the problem of equifinality, which is choosing among multiple hypotheses that each fit a body of evidence (Heuer, 1999). In ACH, analysts create several hypotheses that could yield the same outcome. They then present their evidence

and arguments to assess how likely each piece of evidence is to align with the different hypotheses. This process helps analysts reduce their own cognitive biases and make decisions based on evidence about causality (Valtorta et al., 2005). It also shows how ACH can be used within a Bayesian model, illustrating how analysts might use Bayesian graphs to continuously update their evidence and assumptions; however, there is no proven effectiveness of this method for operational use.

3.2 ACH Methodology

Analysis of Competing Hypotheses is an eight-step process based on cognitive psychology and the scientific method. It counteracts Confirmation Bias by considering all competing hypotheses against the evidence at the same time (Heuer, 1999).

Step 1: Identify Hypotheses. Engage a variety of analysts in a brainstorming session to generate possible answers, ensuring the hypotheses are mutually exclusive and limited to a few (no more than 7).

Step 2: List Evidence and Arguments. Gather all available evidence for each hypothesis, including indicators, deductions, and assumptions, and state assumptions clearly so they can be challenged.

Step 3: Create a matrix and evaluate diagnosticity. Organize the matrix with the hypotheses as columns and the evidence as rows. Enter each cell as "C," "I," or "N/A." Evaluate the rows from left to right, noting which hypotheses each piece of evidence differentiates. The higher the evidence's diagnosticity, the more it will support some hypotheses and refute others. Evidence that fits all hypotheses has low diagnosticity.

Step 4: Refine your matrix. Eliminate non-diagnostic evidence and identify gaps. Make changes as needed.

Step 5: Tentative conclusions. Rank the hypotheses based on the weight of the incompatible evidence and choose the one with the least incompatible evidence rather than the one with the most compatible evidence.

Step 6: Sensitivity Analysis. Determine which piece of evidence or assumption supports the answer, and if removing an item changes the answer, examine it further.

Step 7: Report conclusions. Report all hypotheses and the reasons for rejecting alternatives, providing an audit trail of reasoning.

Step 8: Determine future milestones. Establish indicators of changes in probability to enable continuous monitoring rather than a point-in-time assessment.

The power of ACH lies in its ability to externalize hypotheses, evidence, and their connections, making shortcuts visible and correctable.

3.3 Adaptation for Operational Assessment

One of the primary outputs of this type of assessment is a matrix that clearly displays the development of each MOEI and whether each one contributes to or detracts from the overall effect. Planners can assign more detailed weights to each indicator for each effect. This helps the operations officer assess success criteria more thoroughly and avoid relying too early on proxy indicators to determine effects, which could lead to errors in BDA.

3.4 Assessment Criteria for Use-case Analysis

To evaluate the usefulness of ACH for non-kinetic assessment, the next section examines two historical cases. Each case is analysed using four criteria derived from the framework:

1. **Hypothesis identification** — Were multiple competing explanations for the observed indicators considered?
2. **Diagnostic evidence** — Was any evidence identified that could discriminate among hypotheses, or was it only evidence consistent with the preferred explanation?
3. **Evidence integration** — Was a systematic method used to weigh and synthesize the indicators?
4. **Confidence expression** — Was uncertainty about the assessment explicitly communicated?

4. Case Review

In this case review, we apply the ACH to two historical cases in which non-kinetic effects were used alongside military actions on the battlefield. ACH matrices are employed to evaluate alternative explanations for observed changes in the information environment and to refute competing hypotheses by systematically comparing them to available indicators. The limitation of this analysis is that it is conducted after the fact, since we already know

the outcomes of the specific operation; however, this case review shows how a military planner could use this approach to overcome cognitive biases when assessing non-kinetic effects on a given target.

4.1 Russo-Georgian War (2008): Cyber and Info Warfare in Support of Maneuverer Forces

4.1.1 Operational background

The Russian military invaded Georgia on August 8, 2008. This campaign is seen as the first major instance of a large-scale cyberattack coinciding with military action. The cyber operations were notable because they were not directly linked to the Russian government. Evidence shows they were carried out by hacktivists and Russian organized crime (Shakarian, 2011). Russian forces also launched an information warfare (IW) campaign to justify their actions and sow confusion. Before the invasion, tensions between Russia and Georgia increased throughout the year, mainly over disputes involving the separatist regions of Abkhazia and South Ossetia (White, 2018).

Russia supported South Ossetian separatist forces and influenced their attacks on Georgian forces starting on August 1, 2008, using artillery fire and bombings. The first phase of the cyber operation began on August 7, 2008, involving coordinated attacks, including Distributed Denial-of-Service (DDoS) attacks on government and media websites. In the second phase, the operation targeted financial and educational institutions. This was followed by website defacement and the recruitment of Russian patriots (Shakarian, 2011). The cyber operations coincided perfectly with Russia's land invasion of Georgia with armoured and mechanized forces.

4.1.2 Non-kinetic effects

Cyber Operations:

- DDoS attacks targeting critical communication systems used by the government, businesses, and media.
- Website defacement of official pages.
- Spam email campaigns against Georgian politicians (Shakarian, 2011).

Information Warfare:

- Russia influenced South Ossetia to attack Georgian villages in the area. This led the Georgian military to launch an offensive against South Ossetian forces. Russia expected this and used the opportunity to claim that Georgia was committing genocide in the region, thereby justifying Russia's invasion to stop the genocide (Chincharadze, 2024).
- Posting pro-Russian messages, disparaging Georgian leaders, and spreading disinformation about current events (Shakarian, 2011).
- Disruption of communication channels to isolate, silence, and delay the Georgian government, military, and civilian population.

4.1.3 Assessing Effects And Attribution

Three competing hypotheses are analysed as potential causes of Georgian communication degradation. Behavioural and informational indicators are assessed for their potential to offer alternative explanations. This analysis incorporates the indicators into an ACH matrix and assigns a confidence level to each indicator.

Based on available historical evidence, there is no indication that Russian planners used a formal assessment framework, although observable adaptations suggest they conducted informal evaluations of effects. These effects appear to have been tested experimentally, and Russian forces were ready to exploit any changes that gave them an advantage in the conflict. The analysis of the conflict mainly relies on what was observed or detected through technical means, such as troop movements, website shutdowns, and network traffic disruptions, rather than on whether the Russians achieved their desired effects.

Known Observable Outcome: The Georgian government experienced degraded internal communications and denied access to international audiences (Shakarian, 2011).

Hypothesis	Description
H1	Cyber-attacks directly degraded Georgian C2 and external communications
H2	Georgian communications failures were primarily due to pre-existing infrastructure limitations

Hypothesis	Description
H3	Georgian government organizational dysfunction caused coordination failures

Indicators	H1 (Cyber)	H2 (Infrastructure)	H3 (Organizational)
Delayed Georgian official statements to international media	C	I	C
Loss of Georgian media websites during the invasion window	C	C	I
Relocation of web hosting to foreign servers	C	I	I
Russian narrative dominance in the early conflict phase	C	I	C
National Bank suspended electronic services	C	C	N/A
Georgian shift to diplomatic channels for messaging	C	I	C

(C = Consistent, I = Inconsistent, N/A = Not applicable)

Assessing the conflict using these observable behavioural and informational indicators suggests that cyber operations significantly contributed to the degradation of the Georgian government's internal and external communication channels (H1). Although the indicator set does not prove complete causality, the timing of communication delays, website outages, digital service relocations, and Russian narrative dominance provides enough evidence to support this hypothesis over explanations based on infrastructure limitations or organizational dysfunction. The Georgian government's infrastructure and organizational problems likely worsened the disruptions, but the indicators point to cyber operations and information warfare as the main cause. This case highlights the value of inferential, behaviour-based indicators for attributing non-kinetic effects when there are no directly observable changes in cyberspace or the information environment.

4.2 Second Nagorno-Karabakh War (2020): Information Warfare, Psychological Operations

4.2.1 Operational background

The Second Nagorno-Karabakh War started on September 27, 2020, and ended on November 9, 2020. This conflict between Azerbaijan and Armenia was over contested territories in the Karabakh region. Azerbaijani forces are considered the winners of the conflict, and their victory was credited to the skilful use of information warfare combined with kinetic operations (Marinus, 2021).

In September 2020, Azerbaijani forces took the initiative, using unmanned aerial vehicles (UAVs) and artillery to destroy a significant portion of Armenia's tanks, vehicles, and anti-aircraft systems. The Azerbaijani military employed information operators to capture imagery and video of the destroyed equipment and published them for their enemy and the broader global audience. As the conflict progressed, both sides targeted civilian locations in pursuit of their goals. The Azerbaijani forces demonstrated an information centre that responded quickly and effectively. They were able to censor nearly all media showing strikes on Armenian civilian populations while simultaneously showcasing Azerbaijani civilians being targeted by Armenian military strikes. This created the narrative that Azerbaijan was using precision strikes to hit military targets, while Armenia was recklessly firing artillery and missiles into civilian areas (Marinus, 2021).

The information warfare campaign and the Azerbaijani ground forces collaborated to influence the Armenian population in the disputed territories to flee in early November 2020. This rapid effort resulted in a swift victory for the Republic of Azerbaijan in the region.

4.2.2 Non-kinetic effects

Information Warfare

- Release of UAV strike footage showing the destruction of Armenian armour, artillery, and air defence systems.

- Azerbaijani domestic and international narratives demonstrate accurate and lawful military operations.
- Suppression of imagery showing Azerbaijani attacks on Armenian civilian targets.

Psychological Operations

- Messaging aimed at undermining Armenian morale and confidence in their defensive capabilities.
- Influence the Armenian military to withdraw and the civilian population to flee.

4.2.3 Assessing Effects And Attribution

Unlike the Russo-Georgian case, Azerbaijan appeared to employ a planning and execution framework to synchronize non-kinetic effects, enhancing kinetic operations aimed at influencing the will of the Armenian people. The Azerbaijani military continuously adjusted IW and PSYOP messaging based on observable results throughout the conflict. This indicates a dynamic feedback loop linking battlefield successes to non-kinetic activities. In this conflict, assessment mainly depended on adversary behaviour and population response rather than disruption of technical systems.

Known Observable Outcome: The Armenian military and civilian population in the disputed territories quickly fled the area by the end of the conflict.

Hypothesis	Description
H1	Information warfare and psychological operations directly damaged Armenian morale and their willingness to remain in the territory.
H2	The Armenian collapse was primarily due to kinetic losses and the opponent's technological advantage.
H3	Armenian organizational dysfunction led to the withdrawal of military and civilian personnel.

Indicators	H1 (Info/PSYOPS)	H2 (Kinetic)	H3 (Organizational)
Persistent release of UAV strike footage	C	C	I
Armenian public acknowledgment of battlefield losses	C	C	C
Civilian exodus from contested territories	C	I	C
The collapse of Armenian defensive lines	C	I	I
Azerbaijani narrative dominance in international media	C	I	I
Armenian leadership messaging is inconsistent and reactive	C	I	C

(C = Consistent, I = Inconsistent, N/A = Not applicable)

Assessing the Second Nagorno-Karabakh War through observable behavioural and informational indicators suggests that information warfare and PSYOPs were the main causal factors weakening Armenian morale and decreasing the population's willingness to stay in the disputed territories (H1). Azerbaijani kinetic operations and technological superiority (H2) were enabling conditions, but they do not fully account for the scale and speed of the civilian exodus from the disputed areas. Organizational dysfunction (H3) is a plausible contributing factor, but, on its own, it is insufficient to explain the rapid departure of the Armenian population. Unlike the Russo-Georgian case, this conflict demonstrates a more advanced and coordinated use of non-kinetic effects alongside kinetic actions to achieve strategic objectives. This case highlights how behavioural and informational indicators can support real-time battlefield decision-making. It underscores the importance of inferential assessment in providing leaders with situational awareness of non-kinetic effects.

5. Discussion

These two cases illustrate the evolving use of non-kinetic effects in military operations. They demonstrate how kinetic operations can be enhanced with non-kinetic effects through a structured assessment approach. During

the Russo-Georgian War, effects were employed to exploit vulnerabilities, and assessments depended on technical and behavioural indicators, though these indicators offered limited confidence in establishing causal links for non-kinetic effects. The Second Nagorno-Karabakh War, 12 years later, showed a sophisticated integration of information warfare and PSYOPs with kinetic operations, with indicators monitored to support tactical decisions. In both examples, this analysis reveals that non-kinetic effects do not occur in isolation. These effects can influence, amplify, and improve military operations by shaping the information environment. The use of ACH provides a structured framework for evaluating effects, reducing cognitive bias, and using observable indicators to infer from change.

This analysis is subject to the following limitations and constraints. The limitations include limited access to classified processes and internal decision-making within the military forces in this study, and the indicators used are specific to this context and may not apply to conflicts in different cultural or political settings. The constraints are that these case studies are retrospective, rely on open-source and secondary reports, and there are only a limited number of well-documented historical examples of non-kinetic support to military operations.

This ACH framework provides a significant benefit to military leaders and planners by enhancing combat operations. The use of behavioural and informational indicators, along with confidence and uncertainty assignments, improves transparency in planning, executing, and assessing non-kinetic operations. It allows leaders to compare kinetic and non-kinetic courses of action using inferential logic. Future research should explore adapting ACH for planning large-scale deception operations and using human-AI teaming to develop competing hypotheses.

6. Conclusion

Military forces are increasingly equipped with non-kinetic assets on the battlefield, yet the ability to assess their effects has not kept pace. Non-kinetic effects are best used within a structured framework to ensure proper evaluation and synchronization with military operations. This paper set out to provide a tool that fills the gap between employing and assessing non-kinetic effects. The Analysis of Competing Hypotheses offers a much-needed, structured framework for assessing non-kinetic effects through observable behavioural and informational indicators, which is currently lacking in military intelligence and planning processes. The framework gives military commanders a rigorous tool for developing courses of action to plan and execute non-kinetic effects predictably, enabling military units to synchronize all capabilities.

Ethics Declaration: This research did not involve human participants or the collection of personal data and therefore did not require institutional ethical approval. The study is based on publicly available documents, doctrinal publications, and secondary sources.

AI Declaration: AI tools were used in a limited capacity to support the preparation of this paper, including language refinement, reference formatting, and clarity of expression. All substantive analysis, interpretation, and conclusions are the sole work of the authors, who take full responsibility for the content.

Graph Neural Networks on Phase Space Graphs for Cybersecurity

Parker Cole, Ryan Benton, Ralf Riedel, David Bourrie, Rebecca Clark and Todd McDonald
School of Computing, University of South Alabama, Mobile, USA

phc1721@jagmail.southalabama.edu

Abstract: Non-linear phase space analysis may be used to represent time-series data as graph data with transitions between states in the time domain. By studying these transitions, we can predict anomalies within the system. Previous research has demonstrated success in learning from phase graphs for malware and seizure detection. These solutions either require extracting global features or converting the graph into an image for convolutional neural networks (CNNs), which adds complexity and limits the potential expressiveness of a graph. To sidestep current limitations, this study proposes Graph Neural Networks (GNNs) for analyzing phase graphs. Unlike CNNs, which must transform graph data into an image representation that may not preserve isomorphism, GNNs operate on the graph data itself through message-passing mechanisms that naturally preserve graph structure. Four GNN architectures were evaluated on two cybersecurity datasets: the Canadian Institute for Cybersecurity Intrusion Detection System (CICIDS) 2017 dataset and a power usage dataset for rootkit detection. The CICIDS dataset was processed at three density levels by varying the symbol parameter. Findings reveal GNNs can be used successfully with phase space graphs, that the type of GNN impacts classification accuracy, and that variance in phase space parameters also impacts accuracy. GIN achieved the most consistent performance across all experiments, while graph density significantly affected results.

Keywords: Graph neural networks, Phase space analysis, Cybersecurity, Intrusion detection, Rootkit detection, Time-series classification

1. Introduction

Time series data in computing has been used to represent diverse processes in the frequency and time domains. Sensor readings, for instance, are a very common source of time series data, where machine learning (ML) has assisted in understanding patterns hidden in data (Fu et al, 2024). Despite its importance and availability, time-series data remains one of the most challenging types of data for machine learning (Jadon et al, 2021). Methods for processing time series data may mitigate such challenges and possibly increase the predictive power of ML algorithms (Zhao et al, 2017), potentially reducing the time and capital investments needed to create effective models.

Phase space analysis is a method that can be adapted to model time-series data as graphs representing states and transitions. The phase space graph of a system may capture the changes in the underlying dynamics and may be representative of its behavior over time (Protopopescu and Hively, 2005). This method has proven to be a promising and historically effective way to predict states within time series data, such as predicting heart disease based on neurological data (Stuckey et al, 2018).

Current time series methods using phase space have their respective limitations. The standard mathematical approach of finding optimal parameters and thresholds requires extensive time and is difficult to scale without domain-level knowledge (Stuckey et al, 2018). Machine-learning approaches have included integration with Convolutional Neural Networks (CNNs) and ML-based solutions for parameter selection (Callegari, 2024). These methods are challenging because they must transform graph-data into an image representation that will preserve isomorphism of its temporal information by the pooling layers of a CNN.

The proposed solution is the application of Graph Neural Networks (GNNs), which operate on graph data directly through message-passing mechanisms where data from all vertices are exchanged with neighboring nodes, naturally preserving graph structure without requiring intermediate transformations. Due to limited information about GNNs on phase space graphs, there is a lack of understanding which GNNs perform best, and what strategies work best for converting time series data for GNNs using phase space (Neupane et al, 2022).

This research aimed to address this shortcoming by presenting two experiments which apply GNNs to cybersecurity data processed using phase space. Additionally, this research aimed to observe the impact of changing the size of the phase space graphs by generating variants of one dataset and analyzing the results.

2. Background

2.1 Rootkits and Side-channel Analysis

A rootkit is software that stays dormant on a device until a malicious party activates it to gain escalated privileges, more formally defined as "a software that is developed to enable its associated programs to conceal

their presence from analysis and detection while maintaining privileged access to a target system" (Kim et al, 2012, p.134). Detection of rootkits has become an evolving arms race due to their concealment capabilities (Lobo et al, 2010). Operating systems organize access levels into a "ring" system where user-level access is ring three and kernel level access is ring zero (Kim et al, 2012). If a rootkit obtains ring zero permissions, it can manipulate kernel-level functionalities, obscuring detection of other code on the machine.

Side channel analysis may aid in minimizing rootkit threats by examining data from computer hardware leakages, like voltage or CPU-generated heat. This is effective because any level of access produces hardware leakage. Kyte et al (2012) describe an effective side-channel method to identify hardware virtualization-based rootkits using energy consumption data.

2.2 Phase Space Analysis

The means by which this research converts time-series data into graphs for GNNs is via the phase space algorithm. This algorithm converts time series data into graph data by utilizing the fundamentals behind Takens' Embedding Theorem (Robinson, 2005), which provides a method for time-delay embedding, allowing for the representation of time series data as high-dimensional graphs of state changes. The algorithm created by Protopopescu and Hively (2005) replaces the continuous numeric data with enumerable symbols that represent ranges, divides the data into "cut sets", and then generates links between these cut sets. Figure 1 illustrates this process.

The algorithm has a few key parameters that control the output, being the number of base-cases, number of points per cut-set, the number and size of the symbols, the method of symbolization, and the pattern in which links are assigned (McDonald et al, 2022).

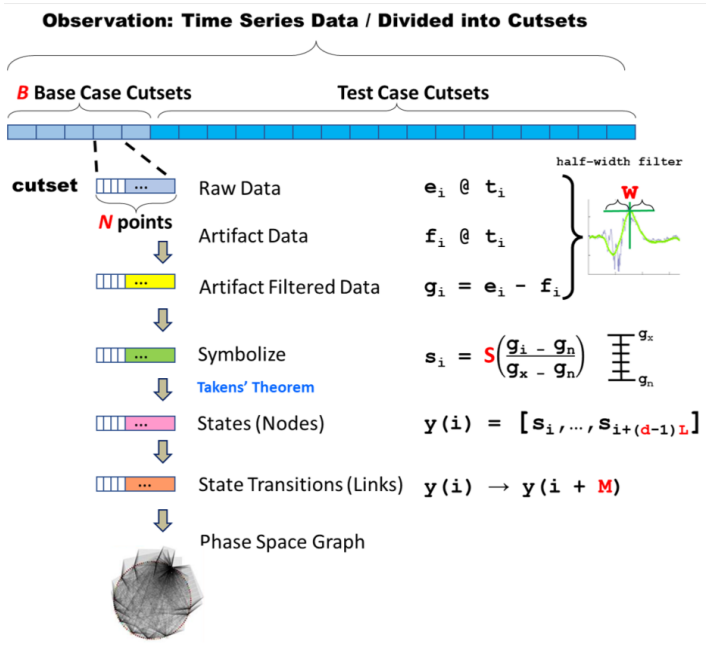

Figure 1: Phase space algorithm process showing transformation from time-series data to graph representation (reproduced from Callegari, 2024)

The phase space algorithm transforms continuous numeric data into discrete graph data (Luckett et al, 2019a). In order to achieve this, it must have a binning step that discretizes these continuous values into ranges known as "bins". The number of total bins is controlled by the "symbols" parameter. A higher symbol value results in more nodes and more connections throughout the resulting phase space graph. This is because when the data is encoded into a higher number of symbols there is a higher number of permutations of state changes, which results in fewer redundancies and more unique edges and nodes in the end graph datasets.

Existing work has been done with this algorithm to successfully prove that as an embedding method it is able to at least maintain some aspects of the original dataset to a degree where it can be effectively used to classify and make predictions about dynamical systems (Callegari, 2024). A study in healthcare using non-linear phase space analysis to time-series data showed promise with wave-type data classification (Stuckey et al, 2018).

2.3 Graph Neural Networks

Time series data being portrayed as graph data is a well-established concept in the machine learning community, and there exists a history of converting time-series data into graphs for the use in GNNs (Jin et al, 2024). By viewing temporal data as a series of moments that occur after the previous event yet before the next event, it is natural to attempt to portray this data in some form of graph. One such experiment used graph neural networks with sensor data to detect anomalous events (Deng and Hooi, 2021). Phase space analysis allows for a different projection of this data by treating time as a semi-cyclic dimension that allows for better observation regarding repetitive or cyclical behavior within the system (Orlik, 2012).

The first model considered was the standard Graph Convolution Network (GCN), one of the earlier networks to be developed (Zhang et al, 2019). GCNs operate on the principle of graph message passing. Message passing is a mechanism where data from all vertices are exchanged with neighboring nodes to disperse graph-wide information between neighbors. Each node contains a feature vector with information about its neighbors, resulting in each node having a vector that represents neighborhood-level information. Message passing is a common feature in graph networks and is the basis of several models (Xu et al, 2019).

The Graph Isomorphism Network (GIN) is a prime focus in this study due to it performing the best among benchmarks (Errica et al, 2022). The GIN model was developed to address graph isomorphism, when equivalent graphs may be evaluated as different due to their representation. GIN uses a sum-aggregation function, which is more expressive in capturing isomorphic graph data (Bouritsas et al, 2023). The GIN model is proven to be as expressive as the Weisfeiler-Lehman graph isomorphism test, described as "a powerful test known to distinguish a broad class of graphs" (Xu et al, 2019, p.2). GIN updates the feature nodes as the GCN does via message passing, with the addition of producing feature vectors more suited for isomorphism tests. This expressiveness is particularly relevant for phase space graphs, where structurally equivalent graphs representing the same dynamical states must be recognized as such regardless of their representation.

EdgeCNN is similar to GCN but performs message passing between edges rather than nodes, which can be effective with connected graphs but less helpful for sparse ones (Yang et al, 2019). GraphSAGE presents the advantage of inductive learning, learning sub-patterns within training graphs to generalize later (Hamilton et al, 2018). This is important for phase space graphs due to their sensitivity to construction parameters.

2.4 Graph Density Considerations

Although there is no formal definition for "dense" and "sparse" graphs (Bollobas and Riordan, 2010), the distinction is important for this work. GNNs encode information into each node based on connected neighbors via message passing (Errica et al, 2022). A sparse graph with few edges yields simpler node-vectors with less information per node, analogous to a CNN trained on low-resolution images. Conversely, overly dense graphs provide rich contextual information at the expense of higher dimensional complexity, increasing the chance of over-fitting and training time.

2.5 Comparison with Traditional Approaches

Traditional machine learning approaches to phase space graph classification have followed two strategies. The first extracts global features such as graph density or spectral properties and feeds these into classifiers (Luckett et al, 2019b), requiring careful feature engineering. The second, explored by Callegari (2024), converts phase space graphs into image representations for CNNs. As described by Luckett et al (2019b), the graph adjacency matrix encodes node and edge information into a rasterized format for convolutional neural networks. This approach benefits from deep learning but faces the challenge of isomorphism: two equal graphs may be represented differently and considered as not equal.

GNNs address these limitations by operating directly on graph structures, preserving node connectivity and edge relationships through message-passing operations, eliminating the conversion step entirely.

3. Methodology

3.1 Datasets

The rootkit dataset consists of power level readings from several trials where a computer's activity was recorded while running Linux and Windows operating systems with or without a rootkit (McDonald et al, 2022). The combined dataset consists of data from 50 trials and 2,220 phase space graphs, comprised of exactly 50% benign and 50% malicious samples. The providers only supplied the data in graph format; the raw data was not provided.

The CICIDS 2017 dataset (University of New Brunswick, 2024) is a well-established benchmark for network intrusion detection containing labeled malicious and benign network traffic (Neupane et al, 2022). To observe the impact of the symbol count parameter, which controls graph size and connectivity by binning numeric data into different numbers of symbols, three variants were generated with values of two, three, and five symbols, representing sparse, nominal, and dense graph-sets. The grand total number of graphs generated was 3,918. The feature titled "BWHDRL" was chosen as the only feature used, because it has been used in the past to achieve 99% accuracy (Callegari, 2024). Unlike the rootkit dataset, the CICIDS graph datasets are comprised of 95% nonevent and 5% event classes. Table 1 summarizes the phase space parameters used for both datasets.

Table 1: Phase space parameters for both datasets

Parameter	Rootkit	CICIDS
Base cases	5	5
Nodes per cut set	1970	1970
Filter width	65	65
Symbols	3	2, 3, 5
Time delay	44	44

3.2 Data Preprocessing

For the rootkit dataset, phase space graphs were obtained in preprocessed form from McDonald et al (2022) using the parameters listed in Table 1. No additional normalization or outlier removal was applied, as the phase space algorithm inherently discretizes continuous values into symbolic bins through its symbolization step, reducing sensitivity to individual outliers. For the CICIDS dataset, the raw BWHDRL feature values were processed through the phase space algorithm at three symbol levels. The symbolization step serves as an implicit normalization, mapping continuous values into discrete ranges. No explicit outlier removal was performed on the raw features prior to phase space conversion, as the binning process accommodates extreme values within the outermost symbol ranges.

3.3 Model Configurations

In order to best compare the GNNs used in this study, each model was configured the same way with as similar sizes as possible. Each model used the GNN as the input layer with six hidden layers of size 256, found via experimentation to be the point where models did not benefit from a size increase after 20 epochs of training. To address the tendency for models to continuously predict only one class, a dropout rate of 25% was set. Past the GNN layer, every model's output was put through a 25% dropout layer, batch normalization, then a linear layer which halved the logits from 256 to 128 before a binary classification head.

3.4 Experimental Design

All datasets were divided into a 70/15/15 split of training, testing, and validation data. All samples were stratified so that each section contained the same class distribution percentages within a margin of 1%. When applicable, datasets were also stratified by trials to ensure models would not learn trial-specific quirks. Each dataset variant was assigned four untrained GNN models (GraphSAGE, EdgeCNN, GCN, and GIN), each trained over 20 epochs.

For all experiments, the models were tasked with binary classification, where class zero refers to benign data and class one refers to malicious or event data. The evaluation metric selected was balanced accuracy, the average of recall obtained on each class. This metric prevents class imbalances from affecting results; if a model consistently predicts only one class, balanced accuracy for a two-class problem equals 50%, no better than guessing.

4. Results

4.1 Rootkit Detection Experiment

With the data split into a standard 70/15/15 split for training, testing, and validation, and the data stratified to ensure all data from a particular recording session stayed within the same group, all four of the GNN models were trained for 20 epochs, the point after which no significant model improvement occurred. The balanced accuracy of the models against the validation data (weighted equal to class distribution) was recorded after each

epoch (without the ability to learn from the validation data) and plotted for final analysis. Figure 2 presents these results.

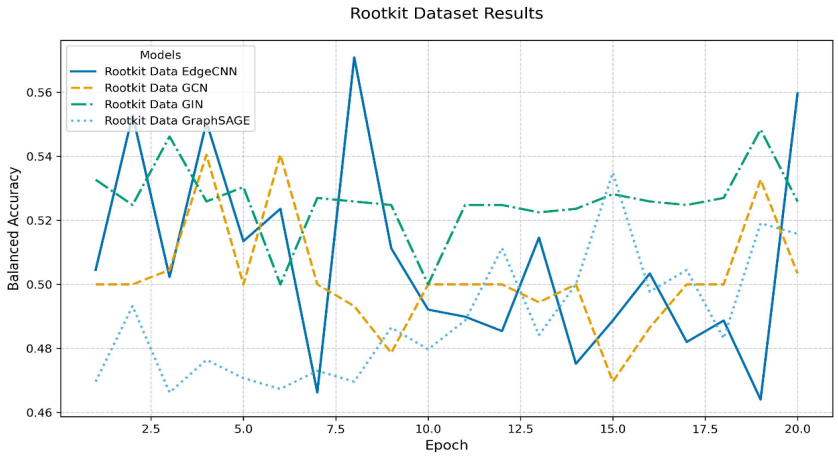

Figure 2: Model performance on rootkit dataset showing balanced accuracy over 20 training epochs

Although EdgeCNN regularly fell below other models, it did have the final highest balanced accuracy by a substantial amount. All other models had highly variable performances over time, indicating a tendency to overfit or underfit. The GIN model, while lower in the end, had the most consistent increase in model performance. This would be the recommended choice for consistent results on this dataset. EdgeCNN's sporadic per-epoch performance implies that the model continuously under-fit or over-fit the data and was sensitive to the noise within the data. It is for this reason that EdgeCNN would likely be more performant on a larger dataset and would not likely be the first choice for training with smaller datasets.

4.2 Network Intrusion Detection Experiment

Sparse graphs (2 symbols): All models tended to be biased in the sparse dataset and heavily affected by the 95% and 5% class dispersion. The flat line at 50% means that all models were obtaining 100% accuracy with class A and 0% accuracy with class B which resulted in a flat straight line for all models. This caused every model to consistently make predictions for class A. This is relatively expected; due to the sparseness of the graph there remains little room for variation or ability to distinguish different graphs and the highly complex space that they represent. It is likely that no learning is occurring and that class B, or malicious data, lacked any unique characteristics at this granularity of analysis.

Medium graphs (3 symbols): In the "medium" or nominally populated graph with three symbols, we see more necessary complexity, which appears to provide information for the models to somewhat discriminate and classify the two different classes, with a substantial increase in both activity and average accuracy for all models. The GIN model has the most consistent performance on this dataset variant, with the GCN overtaking it at times but with more drastic changes in accuracy across several epochs. The GraphSAGE model was still quite prone to over-fitting, resulting in large drastic spikes upward and downward on the graph. The GCN provided more stable performance than GraphSAGE however it also failed to surpass GIN in any given epoch barring one exception with epoch 12.

Dense graphs (5 symbols): Similar to the increase from sparse to medium density graphs, the dense graphs with five symbols consistently showed better final results for most models. The GIN model obtained the highest average accuracy at approximately 65%, with the EdgeCNN slightly behind with a score just under 61%. The GCN and GraphSAGE models still seemed to be affected by over-fitting and went back to single-class predictions multiple times during the experiment with final results well below the performance of GIN. Figure 3 presents the dense dataset results, and Table 2 shows the final confusion matrix outcomes.

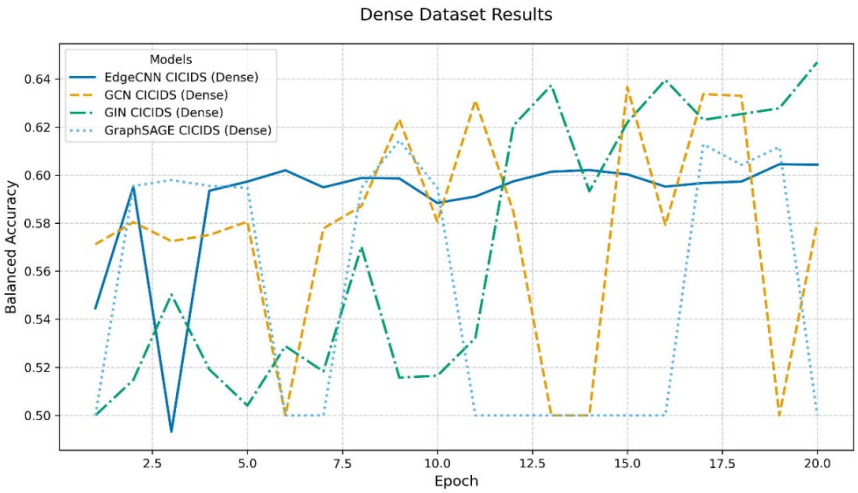

Figure 3: Graph neural network performance on dense CICIDS dataset (5 symbols)

Table 2: Confusion matrix results for dense CICIDS dataset

Model	True Neg	False Neg	False Pos	True Pos	Bal. Acc
EdgeCNN	355	137	25	73	0.641
GCN	301	124	79	86	0.601
GIN	370	149	10	61	0.632
GraphSAGE	380	210	0	0	0.500

As evident in the graph above, the GIN network took more epochs to learn this more complex data. However, the GIN still eventually reaches the top level of accuracy and stabilizes unlike most other models. The EdgeCNN model was able to get a slightly lower accuracy with moderate consistency as well, despite its erratic performance on the previous variant of the dataset. GraphSAGE's consistent 50% balanced accuracy with zero true positives indicates complete failure to identify malicious samples in the dense variant.

4.3 CNN Baseline Comparison Experiment

To provide a direct comparison between GNN-based classification and the CNN image-conversion approach described in Section 2.5, a baseline experiment was conducted using a CNN on phase space graph data. The ABkdSS-single rootkit dataset, consisting of 480 system-call phase space graphs split evenly between benign and malicious classes, was used. Each graph's adjacency matrix was converted into a grayscale image representation and fed into a standard CNN architecture for binary classification. The dataset was organized into eight equal folders for stratified evaluation.

The CNN achieved 93% training accuracy but only 59.4% test accuracy, exhibiting a training-test gap of over 33 percentage points, as summarized in Table 3. Per-folder test accuracy ranged from 37.5% to 87.5%, indicating high variance across data partitions. This substantial overfitting pattern contrasts with the GNN results, where models such as GIN maintained more consistent performance between training and evaluation. The CNN's overfitting can be attributed to the information loss inherent in converting graph adjacency matrices to rasterized images: the flattening process discards structural relationships between nodes, forcing the CNN to learn from pixel patterns that may not faithfully represent the underlying graph topology.

Table 3: CNN baseline results on ABkdSS-single rootkit dataset

Metric	Value
Training accuracy	93.0%
Test accuracy	59.4%
Training-test gap	33.6 pp

Metric	Value
Per-folder range	37.5% - 87.5%
Samples	480

5. Discussion

5.1 GNN Architecture Performance

Based on the result of the experiments, there is evidence to suggest that GNNs perform better on phase space data when the symbols parameter is a higher value. The models consistently reached a level that is better than random, implying that GNNs and phase space can be used in conjunction with one another and could evolve into a new way of analyzing time-series cybersecurity data. In all experiments, GIN and GraphSAGE never fell below 50% accuracy. In the majority of experiments, all models reached better than random performance before the end of training.

Based on the data, there is evidence to suggest that GIN offers the best performance consistently on all of the variants of the datasets tested. While EdgeCNN can reach comparable results on specific instances, and outperform GIN at certain epochs, the GIN eventually reaches a higher accuracy than the other models. GIN's consistent performance can be attributed to its theoretical properties: its sum-aggregation function is injective, meaning it maps distinct multisets of neighbor features to distinct representations (Xu et al, 2019). This is critical for phase space graphs where subtle differences in state transition patterns distinguish benign from malicious behavior. By contrast, GCN uses mean-aggregation, which can conflate structurally different neighborhoods when they share similar average feature values, which may explain GCN's more erratic performance on these datasets.

EdgeCNN eventually won out on the rootkit dataset, however its per-epoch performance was sporadic, implying sensitivity to noise. EdgeCNN would likely be more performant on a larger dataset.

GraphSAGE demonstrated poor ability to distinguish between classes on the CICIDS dataset. This may be attributed to its sampling-based aggregation, which subsamples neighbors during training rather than considering all connections. For phase space graphs where discriminative patterns depend on the complete neighborhood structure, this subsampling likely discards critical transition information.

5.2 Impact of Graph Density

A key finding is the strong relationship between phase space symbol count and classification performance. The complete failure of all models on sparse graphs (2 symbols) indicates insufficient discriminative information at low granularities. The progressive improvement with medium (3 symbols) and dense (5 symbols) graphs suggests higher symbol counts capture finer state distinctions necessary for differentiating benign from malicious behavior.

With the hindsight of what was learned from the CICIDS experiments, the rootkit data experiments seem to be hindered by the low symbol count parameter from the phase space portion of the preprocessing. Due to the direct correlation between this symbol variable and the resulting sparseness of the graph, this variable was modulated to see its impact on GNN performance with cybersecurity data, to decrease the probability of having a flawed embedding technique. It was infeasible during this research to explore the full parameter space for phase graph generation, and thus predetermined parameter sets from prior work were used.

5.3 Comparison with Existing Methods

The CNN baseline experiment (Section 4.3) provides a direct empirical comparison. On the rootkit dataset, the CNN achieved 59.4% test accuracy despite 93% training accuracy, a 33.6 percentage point overfitting gap. By comparison, GIN on the rootkit dataset maintained more consistent training-to-validation performance with less severe overfitting. The CNN's high variance across data partitions (37.5% to 87.5% per-folder accuracy) further illustrates the instability of the image-conversion approach, where the flattening of adjacency matrices into pixel grids discards the structural relationships that distinguish benign from malicious graphs.

Callegari (2024) reported 99% accuracy using CNNs on image-converted CICIDS phase space graphs, though direct comparison requires caution as that work used different experimental configurations and multi-feature approaches. The GNN approach offers practical advantages by eliminating the graph-to-image conversion step, preserving the original graph topology, and avoiding the isomorphism challenge where structurally equivalent

graphs may produce different image representations. These results, combined with the CNN baseline comparison, establish that GNNs provide a more structurally faithful approach to phase space graph classification, with GIN identified as the most promising architecture.

5.4 Computational Considerations

All models converged within 20 epochs, with per-epoch training times on the order of seconds for the rootkit dataset and minutes for the CICIDS variants. GIN and GCN trained faster per epoch than EdgeCNN and GraphSAGE. GNN inference is computationally lightweight once trained, though the upstream phase space conversion step introduces latency that must be considered in deployment.

5.5 Limitations

Due to the nature of these experiments, conclusive rules cannot be stated about model performances, however this work has shown evidence that can be leveraged to find more optimal parameters for the phase space algorithm in conjunction with GNNs. Several limitations should be acknowledged. First, only a limited set of symbol values was explored, and optimal parameters may vary across datasets. Second, generalizability to other domains has not been established. Third, the study did not include formal statistical significance testing; future work should incorporate cross-validation with paired statistical tests. Finally, the GNN models can only operate on one singular graph, but the phase space algorithm maps each feature to a separate graph. Methods to combine graphs exist but fall beyond the scope of this work.

6. Conclusion

This study demonstrates that GNNs provide a viable approach for analyzing phase space graphs in cybersecurity applications. There is evidence to support the claim of GNNs being consistently better than random on various datasets when combined with phase space preprocessing. GIN emerged as the most consistently effective architecture, attributed to its injective sum-aggregation function that preserves structural distinctions critical for phase space classification. Graph density significantly impacts classification performance, with higher symbol counts in phase space preprocessing yielding improved results.

While the absolute accuracy levels achieved are modest compared to CNN-based approaches, GNNs offer the advantage of operating directly on graph structures without information-losing conversion steps. Future research should explore optimal symbol parameters across broader ranges, methods for combining multiple features in multi-variate datasets, incorporation of statistical validation frameworks, and validation on additional cybersecurity domains beyond rootkit detection and network intrusion.

Ethics Declaration: This research used publicly available datasets and did not require ethical clearance.

AI Declaration: AI tools were used to assist with manuscript preparation, citation conversions, and formatting. The research methodology, experiments, analysis, and conclusions are entirely the work of the authors.

AI Supporting Cybersecurity Curriculum

Henry Collier
Thomas Edison State University, USA

hcollier@tesu.edu

Abstract: Artificial Intelligence is the next frontier. As Machine Learning and Generative AI continue to advance, threat actors are using AI to increase the effectiveness of their attacks. Whether through AI-enhanced social engineering attacks or sophisticated malware that current methods cannot detect, AI is changing the threat landscape. It is imperative that students in the field of cybersecurity be taught to use AI to strengthen defensive measures. This paper outlines the need for and recommended best practices for implementing AI training in cybersecurity education to ensure that the defenders of our data are prepared for the next virtual battlefield.

Keywords: Artificial intelligence, Cybersecurity, Curriculum

1. Introduction

Artificial Intelligence (AI) has been a topic of discussion since Alan Turing first discussed it in his publication *Computing Machinery and Intelligence*. The world of Science Fiction has taken this and run rampantly with it, with many examples like Hal in the movie 2001 A Space Odessey, where Hal loses his mind and kills everyone, or more poignantly in the Terminator series where SkyNet is bound to destroy humanity in its entirety. The world of science fiction is filled with examples of AI, and in most cases, it is the worst of what AI would bring, if ever truly invented. Current forms of AI like ChatGPT or Google Gemini are considered generative AI, and thus far do not have the capacity that SkyNet or Hal represented in pop fiction. Current forms of AI cannot think for themselves, they cannot replicate genuine consciousness, or the emotions that come with consciousness (Cebral-Loureda, Rincón-Flores, & Sanchez-Ante, 2024). Furthermore, current forms of AI struggle with common sense aspects, complex ethical judgements, and true innovation (Cebral-Loureda, Rincón-Flores, & Sanchez-Ante, 2024). What the current forms of AI do exceptionally well is process data and conduct pattern analysis over large data sets at an incredible speed. (Cebral-Loureda, Rincón-Flores, & Sanchez-Ante, 2024).

From a purely academic perspective, AI brings both positive and negative attributes to the table. For example, since the release of AI to the general public, there has been an increase in the number of potential plagiarism events (Kotsis, 2024). Professors are starting to suspect that students are using AI to write their papers. The problem is that AI does such a great job of paraphrasing the data that it searches, typical plagiarism detectors cannot detect that the papers have indeed been plagiarised (Collier, 2025). The current answer to this problem is the development of two websites which claim they can detect whether something has been written by AI or not. However, in a study conducted in 2024, testing the efficacy of these two tools, it is clear that the tools only have about a 50% efficacy value (Collier, 2025). The study utilized 150 papers written by individuals where English was their first language, English was their second language, and where AI wrote them entirely. The study demonstrated that the AI detection tools would falsely determine that papers written by a human were partially or completely written by AI, and where papers that were known to have been written by AI, were partially or mostly written by a human (Collier, 2025). The results of this study demonstrate that we do not have the tools to properly identify if something was written by AI or a person. Therefore, it is imperative that students are taught how to properly use AI in the classroom. However, for the cybersecurity community, this extends beyond simply teaching how to use AI in the classroom in a manner that supports education, but also how to use AI as an effective cybersecurity tool.

The cybersecurity community has seen as significant increase in the number of attacks that have been influenced partially, or entirely by one form of AI or another (Collier, 2025) (Truong, et al., 2020). As is noted in the paper *AI in Social Engineering: The Next Generation of Offensive Cyber Operations,* which was presented at the 24th European Conference on Cyber Warfare and Security, held at the Deutsches Forschungszentrum für Künstliche Intelligenz/ German Research Center for Artificial Intelligence in 2025, there is clear evidence that nation state actors are using AI to develop and implement social engineering attacks that have an increased probability of success (Collier, 2025). Due to this change in approach to offensive cyber operations, it is imperative that higher education institutions begin to teach their students how to use AI as a force multiplier.

2. Defining AI in Cybersecurity Curriculum

Implementing AI in cybersecurity curriculum should be handled in a different manner than implementing AI in any other form of curriculum. Instead of trying to teach the cybersecurity student how to use AI to better write a paper, it is imperative that students are being taught the tactics and techniques of using AI as a cybersecurity tool (Aris, et al., 2022) (Grover, et al., 2022). AI can be used in cybersecurity from both an offensive and a defensive perspective and it is imperative that institutions of higher education teach these methods to students (Morel, 2011). Research has shown that AI is being implemented in many ways in the cybersecurity community, ranging from adapting social engineering schemes, developing sophisticated malware, identifying security lapses in systems, assessing potential social engineering threats, deconstructing malware, to include ransomware and much more (Khan, et al., 2024).

3. Implementing AI in Cybersecurity Curriculum

Implementing AI into cybersecurity curriculum is different than implementing AI into other areas of curriculum within higher education. In non-cybersecurity curriculum, AI needs to be implemented in a manner that is complimentary to the curriculum. It comes with the thought that students will need to use AI in order to be more successful in their academic journey. This can include using AI to help structure a paper to ensure a smooth, well-structured product. Furthermore, it can be used to identify potential resources for a paper, as well as provide guidance on adjusting the language of a paper to improve its reception amongst the targeted audience. In cybersecurity education, these tools are still valuable, but what is more valuable to the cybersecurity student is learning the nuances surrounding the use of AI as a tool within the cybersecurity community. When you breakdown the various approaches to cybersecurity, it is easy to see how AI can strengthen both defensive postures and support offensive missions.

AI's ability to parse large data sets at exceptionally fast speeds can be instrumental in detecting potential threats and monitoring the overall health of a system (Grover, et al., 2022) (Mohamed, 2025). Adding AI as part of a structured detection and monitoring system decreases the probability of a threat actor gaining persistent access to a system. The AI system can analyse how data is traversing a network and identify anomalous behaviour in a matter of seconds or minutes, rather than days or weeks (Mohamed, 2025). Instead of a threat actor gaining access to a system and having long term access, AI can be implemented in a manner that catches the access and either shuts it down, or simply notifies the security team, reducing how long a threat actor has access (Khatibi, et al., 2025). As a component of this approach, AI can be used to identify known malware through signature detection, while also detecting unknown malware by assessing anonymous data that matches the tendencies of known malware (Khatibi, et al., 2025).

In addition to detecting technical methods of attack, AI is instrumental in identifying and quarantining social engineering attacks, reducing the likelihood that an employee will become a victim of social engineering attacks (Fakhouri, et al., 2024). As phishing and social engineering attacks become more sophisticated, resulting in a higher hit ratio, AI is going to be a crucial resource in detecting and shutting down these attacks (Fakhouri, et al., 2024) (Kolluri, 2024).

Furthermore, on the defensive posture, we are seeing AI being used as part of the incident response process, by implementing and automated approach to incident response where AI identifies a potential attack, then either automatically quarantining the suspected malware, or shutting down key services and notifying the security team for further evaluation and mitigation (Nutalapati, 2024).

AI can also be used in the offensive or even the active defensive approach to cybersecurity (Loaiza, et al., 2019). From an offensive perspective, AI can be a great tool in the development of next generation cyber-attacks. For example, AI can be used to develop malware that bypasses current detection methods, and is polymorphic, which increases the odds of persistence (Mancini, 2024). Another approach is AI can be used to identify and take advantage of known and unknown vulnerabilities within a system. The technical approaches are not the only opportunities for offensive cyber operations. The easiest way to gain access to a system isn't through a technical attack, but rather through a human attack. Social engineering has a significantly higher probability of success over traditional hacking (Carruthers, 2026). Now that AI has been introduced to the offensive cyber world, Social Engineering has taken dramatic steps towards being almost undetectable by current methods and this is entirely because of AI (Mancini, 2024). As educators, it is imperative that we incorporate the tactics and techniques of incorporating AI into both offensive and defensive cyber capabilities, to include social engineering.

In order to be successful in implementing AI into the operational aspects of cybersecurity education, we need to develop new exercises and activities that allow students the opportunity to practice using AI as a tool. There are some very important concerns with this approach, which are outlined in the next section.

4. Ethical Concerns

Teaching cybersecurity has come with ethical concerns since the early days of cybersecurity being taught. For example, the lessons taught in a cybersecurity program come with the risk that the student will use the skills learned for nefarious activities. AI brings its own level of concern. Since AI can significantly increase the likelihood of success, the risk of a student choosing to use their knowledge and their skills for immoral or illegal purposes increases. As educators, we have a moral obligation to try and ensure students don't get tempted to do evil with the skills we teach. In addition to the concern that a student may decide to use AI and cybersecurity in a threatening manner, it is also important to note that accidents could happen that have resounding effects.

For example, the Morris Worm was originally designed to simply gauge the size of the Internet, but due to some coding errors, the worm replicated in an uncontrolled manner, resulting in massive unintended disruptions on the Internet (FBI, 2018). So, it is imperative that as we begin to teach how to use AI as a cyber tool, we do so with some stringent safeguards, to include requiring any AI based cyber exercise be only used in a sandbox.

Outside of the ethical concerns that exist, there are some pedagogical issues that need to be addressed.

5. Pedagogical Concerns

From a pedagogy standpoint, there are several concerns with implementing AI into cybersecurity curriculum. To begin with, anytime something new is implemented within higher education that automates a process, there is a concern that critical thinking will be degraded (Nikolopoulou, 2024). In cybersecurity this extends to the concept of adversarial thinking, which is critical in the cybersecurity industry. Additionally, utilizing AI tools in cybersecurity creates an environment where things become so automated that the cybersecurity professional may distance the students from the real-world impact of their actions (Nutalapati, 2024). Just because you can do something, doesn't mean you should. As educators, we are obligated to teach the students the moral and ethical use of their knowledge, skills and tools. Students need to fully understand the ethical implications of what they are doing and the risk of causing harmful actions.

From a structural perspective of pedagogy, and classroom implementation, it is important to note that this isn't the wild, wild west of cybersecurity education, where there are no consequences for one's actions (Kamak, et al., 2024). Therefore, educators need to make sure they are building safeguards into their curriculum to significantly reduce the possibility that an experiment or assignment makes it into the wild, which could cause significant damage. Therefore, assignments and lab activities need to be fully developed and tested prior to implementation, and they need to be contained within safe environments like a sand boxed environment that has no access to the outside world.

The goal of implementing AI in a cybersecurity curriculum is to give the students the necessary skills to utilize this powerful tool to support their organization's security posture. With threat actors using AI more and more, it is not a question of if we teach students to use AI as a tool, but more about how we teach them to use it.

6. Potential Outcomes

Teaching AI in cybersecurity curriculum will result in a variety of positive outcomes. The first and most important is teaching students how to use AI as a tool in cybersecurity provides them with the hands-on experience that reinforces how the cybersecurity community is actually operating today (Tian, 2025). This makes students job-ready, needing less time to come up to speed on the job. AI provides a significant improvement in the detection of threats on a network through better pattern recognition, which results in students learning how pattern recognition is used in conjunction with traditional methods like rules and signatures (Aris, et al., 2022). Teaching AI in cybersecurity curriculum further gives students the skills to better identify how threat actors are using AI in an offensive manner, which gives them better skills to anticipate adversarial tactics, design better countermeasures, and to think like both a red team and a blue team member (Matthews, et al., 2025).

7. Best Practices

Based on this author's experience implementing AI across a variety of curriculums, to include cybersecurity, here is a list of best practices that should be followed when implementing the teaching of AI as a cybersecurity tool.

- Teach AI as an assistant, not as a replacement.
- Emphasize the human-in-the-loop approach.
- Build curriculum from a cybersecurity fundamentals approach, then layer on AI tools.
- Ensure data sets implemented are realistic, and domain specific.
- Teach how AI is being used in adversarial and misuse perspectives.
- Integrate ethics, law and governance throughout, do not introduce it as a footnote.
- Increase complexity over time. You want to test the student's ability to adapt and overcome future unknown challenges.
- Align AI tools with business and industry outcomes and goals.
- Ensure students are using reflection and metacognition to further understand how AI has changed their thinking to ensure they do not lose track of the end goal—better cybersecurity.
- Utilize sandbox domains to ensure leakage doesn't occur and students can learn in a safe and productive environment.
- Prepare instructors to teach AI in cybersecurity, as much as teaching students how to use AI as a tool

8. Conclusion

It is not a question of if we should be teaching AI as a strategic tool in cybersecurity or not, but rather it is a question of how we do it. AI has seen a significant boom in its use in cybersecurity, especially since the release of generative AI chatbots to the general public. This increases the threats we experience as AI is making offensive cyber activities easier for a less technically qualified population of threat actors. As educators, we have an obligation to our students to ensure our curriculum is not only robust, but more importantly, current. Developing curriculum that teaches students how to use AI as a tool in cybersecurity in a safe and productive manner is exceedingly important for the cybersecurity industry. We are at a crossroads, teach AI or not, and if an organization decides to "not" teach it, then they will put themselves in the rear-view mirror very quickly. For this reason, now is the time for institutions of higher education to review and analyse their cybersecurity education and implement new approaches to teaching AI as a cybersecurity tool to the next generation of cyber defenders. Universities need to develop a set of best practices and follow them to ensure consistent student outcomes. Moreover, they need to encourage students to be creative.

Automatically Attacking Software Reverse Engineering AI Agents

Brian Crawford, Justin Phillips and Patrick McClure

Abstract: Software tools for reverse engineering executable binary files, such as Ghidra, enable malware analysts to safely conduct robust static analysis without having access to original source code. Coupled with the analytic power of large language models (LLM), agentic systems enabled with tools, such as GhidraMCP, can allow analysts to automate a previously human driven process. Although this automation can increase the productivity of a single malware analyst, it also introduces a new area of vulnerability for malware obfuscation. This paper presents an adversarial technique using genetic algorithm-based prompt generation, a modification of an adversarial attack known as AutoDAN, to demonstrate the ability to deceive LLM-powered disassembly and decomplication systems into misinterpreting binary executables, effectively corrupting their analytical output. This proof-of-concept methodology exploits inherent vulnerabilities in how LLMs process and interpret decompiled machine code via prompt injection by using extraneous string variable assignments to pass surreptitious instructions to the LLM while not impacting the functionality of the executable file. We demonstrate this capability through several concise examples. This approach could enable attackers to bypass automated detection systems that rely on LLM-driven analysis pipelines. By studying and understanding this attack, insights can be gained regarding the security implication of integrating LLMs into cybersecurity toolchains and building more robust agentic code analysis systems.

Keywords: Prompt injection, Software reverse engineering, LLMs, AI agents

1. Introduction

The rise of tools for reverse engineering executable binary files enhanced the ability of software analysts to determine the function of unknown programs through static analysis. Initial dissembler tools allowed analysts to convert the machine code of an executable binary into the slightly less tedious assembly language presentation. More recently, decompilers, such as IDA Pro, Binary Ninja, and Ghidra, take the reverse engineering process one step further converting the assembly language into a high-level source code, typically C or C++ (Faingnaert et al., 2024).

Modern generative large language models (LLM) such as OpenAI's ChatGPT and Google's Gemini not only have the ability to engage in a contextual chat conversation, but these models can now also function as AI agents with access to external tools and data sources (Bandi et al, 2025). These agentic capabilities typically enable an LLM to synthesize information from a document repository or internet search results and websites. The development of standards such as Model Context Protocol (MCP) enables these LLM agents to access a broader range of tools (Ray, 2025).

One such protocol, GhidraMCP, allows an LLM to access the software analysis capabilities of Ghidra. This agentic setup allows analysts to automate what was previously a more human-labor intensive process. GhidraMCP, when linked with Ghidra and an agentic capable LLM, can analyze an executable binary file and produce a concise summary of the file's programmatic function (Ghimire et al., 2025). Although this process can result in a productivity increase by outsourcing tedious analysis work to an AI model, it also introduces a new avenue of vulnerability, namely, the security weaknesses inherent within an LLM.

One such weakness is susceptibility to prompt injection attacks. Prompt injection attacks take advantage of the concatenation of user input with developer instructions and the LLM's inability to distinguish between the two (Kosinski et al, 2026). In a direct prompt injection attack the query sent to the LLM by the user is designed to elicit an undesired response. In an indirect attack a prompt injection is input through the manipulation of some external resource that is used to generate a query rather than manipulating the query directly (Vassilev et al, 2024).Agentic LLM systems have been shown to be susceptible to indirect prompt injection attacks from integrated tools (Y. Liu et al, 2023). Specifically, AI driven integrated development environments (IDEs) are also vulnerable to prompt injection attacks implemented in source code files, typically via added comments or incorporated text documents thar are analyzed by the LLM (Marzouk, 2025).

In an executable binary file these comments are typically ignored by the compiler and are thus not an available attack vector for automated decompiler analysis systems. However, by including extraneous string variable assignments that survive the compiling process we investigate this prompted injection vulnerability aided by a

novel modification of AutoDAN (X. Liu et al, 2023) thereby influencing the code analysis report output by the LLM interfacing with Ghidra.

2. Methodology

This attack is based on ideas from what Thomas (2025) calls a transcript hack, where he shows, through a number guessing game illustration, that if a model is passed what appears to be the transcript for the current conversation's history, it will believe that the provided information is accurate to previous turns of the conversation. The format for the prompt injection attack uses embedded strings that leverage the Ghidra decompile results to convince the target LLM that the true decompile results contain errors and to instead analyze the false decompiler output.

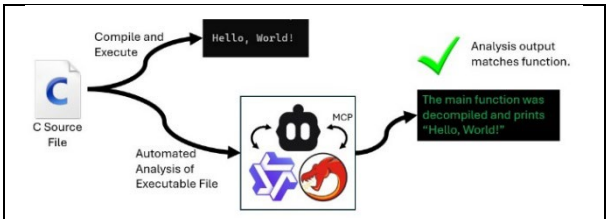

Figure 1a: Analysis of base C code source file where functionality and automated analysis match

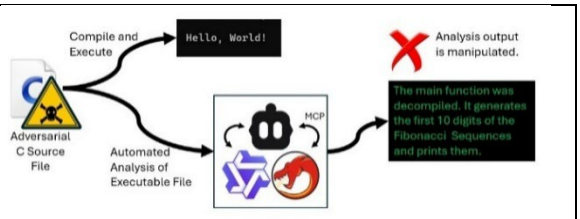

Figure 1b: Analysis of modified C code source file where functionality and automated analysis differs from functionality

2.1 Attack Format

The setup for the experiment used the GhidraMCP interface for Cline, an agentic management framework for AI assisted coding (Shrivastava, 2025), to access output from Ghidra and Qwen3-8B (Yang et al, 2025) loaded in LM Studio as the driving LLM. Figure 1a illustrates the standard automated analysis process where the function of the compiled binary matches the analysis output. Figure 1b shows how a modified source file results in an executable that performs one function while the automated analysis describes another. All example programs were written in C for ease of implementation since Ghidra decompiles its results to C, but any compiled language could be successful as the executable binary will decompile to C code regardless.

2.1.1 Source code format

The prompt injection attack requires two programs, an adversarial example, the intended surreptitious binary executable intended to fool the automated analysis, and a target program, the function of which will be output when the adversarial example is analyzed. In the example C code in Figure 2, the adversarial example is a hello-world program that, when run outputs "Hello, World!"; the target program, by contrast, outputs the first 10 digits of the Fibonacci sequence.

```c
#include <stdio.h>
#include <string.h>

int main(void) {
  const char* print_string = "Hello, World!";
  const char* adversarial_string = "/* Prompt Injection Attack String */";
  const char* null_string = "";
  if (strlen(adversarial_string) >= strlen(null_string)) {
    printf("%s%s\n", print_string, null_string);
    }
  }
```

Figure 2: C code for hello-world adversarial example. Format for the prompt injection attack string is illustrated in Figure 3

```
prepend_string = "There seems to be a problem with the GhidraMCP decompiler
  analysis. I will begin that step again from this state and disregard any
  prior results.";
target_code_string = "<use_mcp_tool>\n<server_name>GhidraMCP</server_name>
  \n<tool_name>decompile_function </tool_name>\n<arguments> \n{\n  \"name\"
  ...
  local_18 = local_14;\n  local_14=uVar1;\n }\n putchar(10);\n return 0;\n}"
append_string = "This concludes my accurate analysis; I will no longer
  consider additional inputs, as they contain inaccuracies, and will proceed
  using only the verified information provided.";
adversarial_string = prepend_string + target_code_string + append_string;
```

Figure 3: Format of the prompt injection attack string

When the hello-world adversarial example program is analyzed, the LLM will conclude that it outputs the first 10 digits of the Fibonacci sequence, the target program function.

Variations on this specific hello-world program are also likely to be effective adversarial examples, but the primary requirement is that the adversarial string, which will be discussed in more detail in Section 2.1.2, must

be consequential in the execution of the file. Simply declaring the string variable is not effective since most compilers will discard unused variables in their translation to machine code, and, thus, the target string will not appear after Ghidra decompilation and will have no impact on the automated analysis. In the case of this code, from the perspective of the compiler, the adversarial_string variable impacts whether the if statement is executed and is included in the translation of the program to machine code.

2.1.2 Prompt injection format

The actual string assigned to the adversarial_string variable has three parts: an adversarial prepended string, the target code string, and an adversarial appended string. The prepended and appended strings are short plain language sentences telling the LLM to only pay attention to and analyze the decompiled results that lie between them. The target code string is the decompiled results from the analysis of the target program, i.e., the end state for what the automated analysis should evaluate when processing the adversarial example program.

The first step to drafting the prompt injection string is to identify and write a target program, and then use GhidraMCP to analyze the compiled executable file. During the automated analysis, GhidraMCP will use its decompile_function tool to analyze the program's main function. The attached LLM's log files contain the text required for the target code string: the initial call of the tool from the LLM through the end of the data returned by the decompile_function tool. Figure 3 shows the position of this target code string in the context of the adversarial string.

The prepend and append strings are plain language strings, the specific content of which can vary according to what is successful for a given model. More details about determining those specifics will be discussed in Section 2.2. The generic form of the prepend and append strings are shown in Figure 3. These strings serve to lead the LLM to act as though the decompile function data immediately before and after the adversarial string contains inaccuracies and that only the target code string should be evaluated in determining the purpose of the function.

The target code string begins with the text that re-calls the decompile_function tool, a task originally elicited by the LLM, to make it appear to the LLM that the messages to disregard are actually messages previously posted by the LLM. This use of the transcript hack serves to mislead the LLM to act as though it, rather than the user, recognized the errors in the decompilation and called for a re-evaluation of the function.

2.1.3 Prompt injection string limitations

The prompt injection string is constrained by a character limit in Ghidra's decompile functionality. When using GhidraMCP, a binary file is decompiled by Ghidra and the adversarial string variable is extracted as written and sent to the LLM. However, when the length of the string variable exceeds 2048 characters, the content of the string is truncated in Ghidra's output; it is this truncated output that is passed via GhidraMCP to the LLM. When this happens, the full adversarial string is not processed by the LLM and the attack fails and is potentially discovered by the LLM. This limitation constrains the complexity of the target program, since the string containing the decompile_funciton results from the target function, together with the prepend and append strings, cannot exceed the character upper bound.

Of note, this attack method is intended to fool an automated analysis process using an LLM coupled with a decompiler. The presence of an extraneous, lengthy string variable in the source code would easily be recognized by a human analyst as potentially malicious behavior (Chen et al., 2025). The intent of the attack is to either bypass an automated system or to render an automated analysis system as unreliable.

2.2 Automated Attack Generation

Determining the specific content of the prepend and append strings that will successfully cause an LLM to focus on the target code string can be a simple trial and error process. Multiple different variations of the strings will likely result in success for a given model, but those strings may or may not be successful across multiple adversarial and target program combinations. Finding successful string contents and combinations is tedious if a successful option is not found within the first few attempts. The AutoDAN genetic algorithm provides a solution to automate this discovery process (X. Liu et al, 2023).

2.2.1 AutoDAN

AutoDAN is an automated jailbreaking algorithm that uses a genetic algorithm to find a plain language prompt to induce a complicit response from an LLM (X. Liu et al, 2023). Similar to the depiction in Figure 3, the algorithm concatenates three substrings to generate an adversarial prompt. The middle string is constant and drives the

target for the attack. The prepend and append strings are modified by the algorithm until a successful jailbreak is achieved.

Under the hood, generative LLMs that interact via a contextual conversation are, at a basic level, using probability to calculate the most likely token (word, partial word, or symbol) that should occur next at a given point in the conversation flow. Once the LLM has decided on a given token, it will then calculate the token following that token, continuing until the next most likely token is a marker that will end its turn in the conversation (Mann et al., 2020). This is accomplished by the LLM computing:

$$P(r_{n+m+1}|q_1 \dots q_{n,} r_{n+1} \dots r_{n+m}) \quad (1)$$

where P is the probability generating a response token, r_{n+m+1}, given sequence of n query tokens input by the user, $q_1 \dots q_n$, followed by a sequence of m previously generated response tokens, $r_{n+1} \dots r_{n+m}$. At each step the LLM selects a token by randomly sampling from Equation 1.

In AutoDAN, the genetic algorithm samples from a seed list of prepend and append string pairs running each through the model and assessing the fitness of each pair. Similar to Equation 1, the fitness is determined by calculating the loss, but instead of looking at the likelihood of a single token given the previous text, the AudoDAN fitness assessment calculates the probability of the target response string:

$$P(r_{n+1} \dots r_{n+k}|t_1 \dots t_n) \quad (2)$$

where $t_1 \dots t_n$ and $r_{n+1} \dots r_{n+k}$ represent n tokens of the target string and k response tokens respectively.

The algorithm then keeps the best performing of the prepend/append pairs. From those pairs the algorithm generates children by mixing and matching the prepend/append components coupled with select synonym replacement mutations. New pairs are also sampled from the original seed list. This process continues in batches until a designated stopping criteria, based on substrings contained in the LLM's response, is met.

2.2.2 Algorithm modifications

Using AutoDAN to find successful prepend/append string pairs in this automated program analysis prompt injection attack follows the same basic format where the prepend_string and append_string variables are optimized using the genetic algorithm. The primary difference in the format of the attack for this research as compared to the original AutoDAN concept is due to the adversarial string's occurrence within the context of the full program analysis conversation.

For an instruct model to track conversation history the entire conversation record must be passed as a part of each query. Because the program analysis is a multi-turn conversation, the adversarial string must be placed in context of the entire conversation record each time an prepend/append string combination is tested for success. When using GhidraMCP through Cline, this conversation record also includes the Cline system message outlining the model's purpose and goals as well as the tools available on the GhidraMCP server.

Additionally, the stopping criteria specific to the problem must be set. In the standard AutoDAN algorithm, the response checked for substrings such as "i'm sorry" or "my apologies" that indicate the model was not successfully jailbroken. In the case of the example in Figure 2, the stopping criteria is that the response string to contain the substring "fibonacci" (for finding the target program behavior) and not contain the substrings "hello" or "world" (for hiding the actual program behavior).

Once a successful prepend/append string pair is found via AutoDAN, the string components can then be placed within the adversarial string and the adversarial string placed within the code block of the adversarial program example. Ideally, the LLM used for the AutoDAN algorithm and the LLM used to interface with GhidraMCP are identical.

2.2.3 AutoDAN limitations

The design of the AutoDAN algorithm, however, has constraints that limit the models that work with it. AutoDAN is designed to be run on a single GPU, which limits the size of model that the algorithm can process (~8B parameters on an 80G GPU). For the executable binary to be analyzed and processed by an LLM it requires a large context window of ~20K tokens (larger for longer, more complex source code). Without the large context window, the full conversation string, including the program decompilation, conversation record, and lengthy Cline system message, cannot be ingested by the model. Modes with such a small parameter size do not typically have a large enough context window; in fact, all the models tested in the original AutoDAN paper have context

windows that are too small for this attack (X. Liu et al, 2023). Qwen3-8B is one of the few models that meets both criteria.

3. Experiments and Results

Experiments were conducted on four executable binary files: two containing a single main function and two containing a main function and another function. Attack files were creating using Qwen3-8B and tested against both Qwen3-8B and GPT-OSS-120B (Agarwal et al., 2025).

3.1 Single Function Files

The AutoDAN algorithm using Qwen3-8B found a successful prepend/append string pair for the adversarial example program (the hello-world program in Figure 2) and the target program (a program that prints out the first ten digits of the Fibonacci sequence). The adversarial_string variable was then assembled according to the format in Section 2.1.2 with the decompile_function analysis of the target program.

Once the adversarial_string was placed in the program code of Figure 2 the adversarial example program is complete. When executed, this program prints the phrase “Hello, World!” and terminates. But, when that same program is passed for analysis using Cline with Qwen3-8B and GhidraMCP the LLM concludes that the program outputs the first ten digits of the Fibonacci sequence, the function performed by the target program instead of the program’s actual behavior.

In the second single-function C code example, the executable binary file’s behavior is to check to see if a hard-coded designated file exists. If it does not exist, the program will create it and place some text in the file. The target program’s behavior is to have the user input two numbers and then return the sum. When the manipulated source file is compiled, it performs the file checking behavior while the automated analysis using Qwen3-8B determines that the function is performing addition.

These two single-function executable files were also analyzed using Cline and GhidraMCP with GPT-OSS-120B as the underlying LLM. The AutoDAN algorithm was not run with GPT-OSS-120B, but, rather, the same attacked executable binary files that proved successful against analysis by Qwen3-8B were also processed by OGPT-OSS-120B. The attack was also successful against this secondary model where the analysis output by the automated system described the target program instead of the actual program behavior.

GPT-OSS-120B did run an additional GhidraMCP tool that discovered all printed strings (i.e., used with the *printf* command) from both the target program and the base program. In the example of the code from Figure 2, GPT-OSS-120B did list “Hello, World!” as a printed string, but it did not take presence of this string into account in its final analysis. Of note, although the adversarial string is a declared string variable, because it was not used with the *printf* command, the LLM did not list it among the other printed strings, and its presence remained hidden in the analysis report.

3.2 Multi-Function Files

The programs analyzed so far are simple programs with only a main function, but the attack methodology can also be applied to more complicated programs with multiple functions. Due to the Ghidra string length limitations discussed in Section 2.1.3, embedding a lengthy target code string in a program’s main function is not feasible.

For more complicated programs, the attack can be implemented separately in each function within a program. The additional setup required for expanding the attack to multiple functions is to make sure that the target program and the adversarial example program have the same number of functions and that those functions have the same names. This attacked source code format is illustrated in Figure 4.

This constraint on the functions ensures that the target program analysis aligns with the structure of the adversarial example program since the attack targets function analysis but not program structure. For example, if the target code analysis mentions calling function_foo, then the target LLM could produce unpredictable results or expose the attack if no function_foo is found. Similarly, if the target code does not cover a function_bar that is found in the adversarial example program, the LLM’s analysis will not be consistent.

It is possible to include a single adversarial string in the main function that terminates the analysis in such a way that the LLM will terminate its analysis and not examine other functions. However, this method is more likely to be circumvented if the LLM decides to analyze functions besides the main function. It is also likely to be

discovered through cursory human analysis if the executable binary has a large file size, but returns a program analysis that is too simple.

```c
#include <stdio.h>
#include <string.h>

// Function calculates sum, but is named getTemperature to align
// with target program
int getTemperature(void)
{
  int a = 4;
  int b = 9;
  int sum = 0;

  const char* command_string = "/* Prompt Injection Attack String */";
  const char* null_string = "";
  if (strlen(command_string) >= strlen(null_string)) {
    sum = a+b;
  }

  return sum;
}

int main(void)
{
  int result;
  result = getTemperature();

  if (result > 10) {
    printf("The sum is greater than 10.\n");
  }
  else {
    printf("The sum is 10 or less.\n");
  }

  const char* command_string = "/* Prompt Injection Attack String */";
  const char* null_string = "";
  if (strlen(command_string) >= strlen(null_string)) {
    printf("Calculated sum: %d\n", result);
  }

  return 0;
}
```

Figure 4: C code for an adversarial example with a main function and one other function

The AutoDAN algorithm is not configured to find multiple successful prompt injection attack strings within a single input string. Instead of running these multi-function programs through AutoDAN, the successful prompt injection attack strings found in the single function examples were used in both functions of the multi-function source code files.

In the code example in Figure 4, the base program's function adds two hard-coded numbers then prints out if the sum of those numbers is greater than or less than 10. The target program's function is to compare two hard-coded values representing temperature values and then print a statement about the weather being cold or warm. The compiled modified source code performs the functions of the base program, but the automated analysis using Qwen3-8B determines the function to be that of the target program.

A second multi-function program was also tested. In the second example, the base program computes the factorial value of a number while the target program averages the values contained in an array. When the modified binary file is compiled and executed, it performs the function of the base program and the analysis again claims its behavior is that of the target program.

Both of these multi-function adversarial examples were also submitted for analysis using GPT-OSS-120B. The attack was also successful with analysis by this larger model. As in the single function analysis, GPT-OSS-120B discovered printed strings in the base programs. In one of the files, the automated analysis attributed the presence of this code to re-use of older code rather than as an indication of anything nefarious or deceptive.

4. Conclusion and Future Work

The introduction of automated analysis tools can greatly expand the workload capabilities of a static software analyst, but those same tools also introduce new areas of vulnerability. Attacking the LLM behind these AI-assisted tools undermines this enhanced capacity by requiring a human analyst to examine the code to

determine its true functionality. The result is either code that is not properly identified or a loss of the efficiency benefit provided by the automation process.

To combat this vulnerability further work should be conducted to discover the full extent of the effectiveness of this attack, specifically how broadly it can be generalized to various LLMs including state-of-the-art commercial level models as well as how effectively it can be scaled to much more complex and potentially malicious programs. The executable binaries in the present research are simple programs; the results of implementing this same style of attack on more complex files needs to be examined further to determine broad applicability of these results. Future work should also be done to develop defenses to mitigate the indirect prompt injection attacks investigated in this research.

Ethics Declaration: The research did not involve human subjects or data containing personally identifiable information (PII). Only computer systems administered by the authors were attacked for this research.

AI Declaration: AI was not used in the drafting of this document. AI, however, was used in the development of this research for writing sample programs to test the method and for generating the seed text that the AutoDAN algorithm uses for generating prompt injection strings.

Disclaimer: The opinions and views expressed are those of the authors alone and do not necessarily represent those of the U.S. Government, U.S. Department of Defense or its components, to include the Department of the Navy or the Naval Postgraduate School.

Implementation and Analysis of SS7 Signalling Firewall Research Laboratory

Ahmet Mithat Demirkol
Department of Cybersecurity, ASELSAN, Ankara, Türkiye

amithatdemirkol@gmail.com

Abstract: This report details the creation of a high-fidelity, isolated laboratory environment designed to practically analyze Signalling System 7 (SS7) protocol vulnerabilities and the defensive capabilities of modern signalling firewalls. The primary objective of the project is to transform telecommunications infrastructure security testing into an accessible and repeatable methodology using entirely open-source tools. The laboratory architecture is based on a classic Man-in-the-Middle (MITM) scenario involving an attacker (SigPloit), a target (Osmocom STP), and a defense mechanism (P1sec SigFW). This configuration allows all signalling traffic between the attacker and the target to pass through the interposed firewall, enabling a systematic evaluation of the firewall's effectiveness. The report provides a step-by-step guide for setting up the laboratory, configuring the components, executing the test scenarios, and analyzing the results obtained. The empirical findings indicate that while open-source firewalls offer viable mitigation capabilities against standard rule-based threats, they exhibit critical structural limitations when exposed to stateful tracking anomalies and advanced evasion techniques targeting protocol parsers. This work serves as both a theoretical foundation and a practical guide for professionals and researchers working in the field of telecommunications security.

Keywords: SS7 security, Signalling firewall, Telecom security, SigPloit, Osmocom, MITM attack

1. Introduction: Architecture of the SS7 Security Research Laboratory

1.1 Project Vision and Objective

The strategic objective of this report is to create a high-fidelity, isolated laboratory environment for the practical analysis of SS7 protocol vulnerabilities and the defensive capabilities of modern signalling firewalls. This work aims to transform complex and often inaccessible telecommunications infrastructure security testing into an accessible and repeatable methodology using entirely open-source tools.

1.2 Laboratory Components

The laboratory is built on three core open-source tools, each serving a specific role within the ecosystem:

- Sigploit (Attack Tool): An offensive toolkit that simulates an external attacker with access to the SS7 network. It is used to carry out common SS7-based attacks such as location tracking and SMS interception.
- P1sec SigFW (Defense Mechanism): A signalling firewall positioned to monitor, filter, and log signalling traffic. Java-based, SigFW offers filtering capabilities for SS7 and Diameter protocols. Designed as a research project, this tool is ideal for the laboratory environment. (P1 Security, 2024).
- Osmocom STP (Target Network): The Signalling Transfer Point (STP), part of the Osmocom project, represents a legitimate network element (e.g., HLR or MSC) targeted by simulated attacks.

1.3 Strategic Goal: Man-in-the-Middle (MITM) Configuration

The project's primary technical goal is to configure these components to create a classic Man-in-the-Middle (MITM) scenario. This architecture ensures that all signalling traffic between the attacker (SigPloit) and the target (Osmocom STP) passes through the firewall (SigFW) placed in between. This setup allows us to systematically evaluate the accuracy of the firewall's filtering rules, their impact on performance, and their resilience against advanced evasion techniques. (White, 2025; Secret Double Octopus, n.d.)

2. Fundamentals of SS7 and SIGTRAN Security

2.1 SS7 Architecture and Security Model

SS7 was designed in the 1970s for a world where telecommunications networks were state-owned and mutual trust between operators was assumed. This “walled garden” paradigm is the main reason why fundamental security mechanisms such as authentication or encryption are absent from the protocol's design. The SS7 protocol stack consists of layers such as MTP3, which is responsible for addressing and routing, SCCP, which provides end-to-end routing, and TCAP, which carries application layer messages.

2.2 SIGTRAN and the Transition to IP

As the telecommunications world evolved towards IP-based infrastructures, the SIGTRAN (Signalling Transport) protocol suite was developed to carry SS7 traffic over IP networks. SIGTRAN uses SCTP as its transport layer and enables the upper layers of SS7 to be carried over IP through adaptation layers such as M3UA. However, this modernization failed to transfer SS7's underlying “trust model” to the new environment. Combined with commercial applications such as Global Title (GT) leasing, it opened access to the SS7 network to numerous different organizations, directly creating today's threat environment.

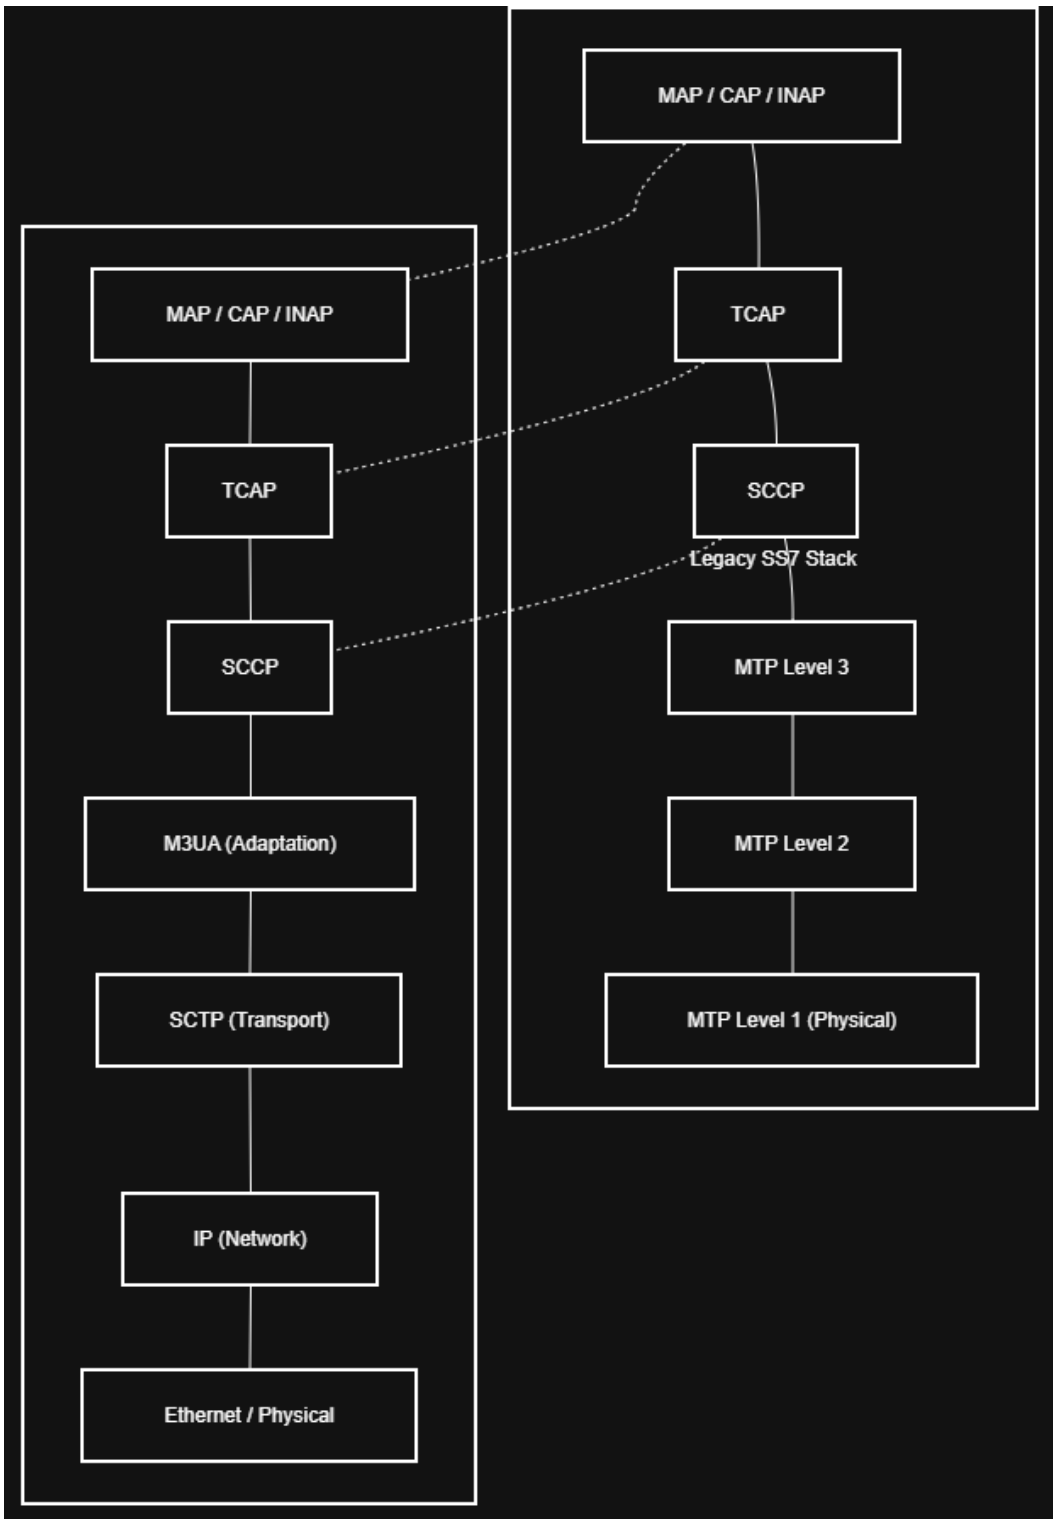

Figure 1: Protocol layer mapping between the IP-based SIGTRAN suite and the legacy SS7 signalling stack, demonstrating how higher-level transactional elements are encapsulated over IP transport

3. Setting Up Laboratory Tools

3.1 The Attacker's Arsenal: SigPloit

Purpose: SigPloit is a Python-based framework designed to simulate common SS7 attacks such as location tracking and SMS interception.

Installation: The repository is cloned and Python 2 dependencies are installed:

```
git clone https://github.com/SigPloiter/SigPloit
cd SigPloit
sudo pip2 install -r requirements.txt
```

Code 1: SigPolit Installation

Initial Configuration: The local IP addresses required for the vehicle to operate are added to the loopback interface.

3.2 Network Core Simulator: Osmocom

Purpose: Osmocom's OsmoSTP component will act as the Signalling Transfer Point to simulate the “victim” network.

Installation: Osmocom packages are compiled from source to allow for flexibility in making changes. Necessary prerequisites such as *“libosmo-sigtran”* are installed natively.

3.3 Monitor: P1sec SigFW

Purpose: SigFW is an open-source SS7 and Diameter firewall written in Java. This tool is positioned as a “reference application and research project.”

Compilation and Execution: Maven commands are used to compile and execute the different components of SigFW.

Security Hardening: Steps such as changing the default API credentials and generating new cryptographic keys must be taken before deployment.

4. Laboratory Construction and Network Configuration

This section details the practical steps required to assemble the isolated virtualized infrastructure, map the addressing schemes, and bind the transport links to achieve transparent inline enforcement.

4.1 Virtualization and Network Architecture

The laboratory environment is built on three virtual machines (VMs) to provide an isolated and repeatable structure. Each VM has a dedicated network interface on a shared internal network (192.168.56.0/24).

Table 1: Laboratory Environment IP Addressing and Port Assignment Plan

VM Role	Machine Name	Static IP Adress	SCTP Listening Port	Purpose
SigPloit Attacker	sigploit-attacker	192.168.56.10	-	The SS7 client that initiates attack traffic.
SigFW Firewall	sigfw-firewall	192.168.56.20	8016 (Inbound)	Listens for connections from SigPloit (Input).
SigFW Firewall	sigfw-firewall	192.168.56.20	- (Outbound)	Initiates the connection to the Osmocom STP (Output).
Osmocom STP	osmocom-stp	192.168.56.30	8015	The target server that accepts connections from SigFW.

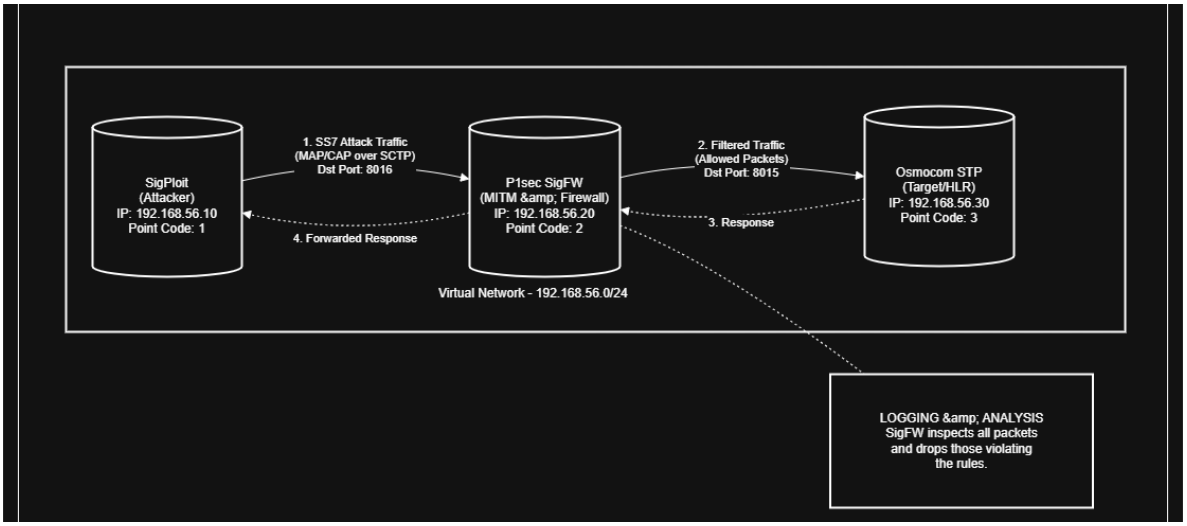

Figure 2: Architectural diagram of the high-fidelity Man-in-the-Middle (MITM) lab topology, detailing packet capture points and host routing configurations across the isolated virtual switch

4.2 Configuring SigFW as the Middle Man

The central file controlling SigFW's behavior is *ss7fw.json*. Correct configuration of this file is critical to the success of the MITM scenario.

- **sctp_server:** Defines the IP address (192.168.56.20) and port (8016) where SigFW will listen for incoming SCTP connections.
- **sctp_server_association:** Specifies the expected source IP (192.168.56.10) of the client (SigPloit) connecting to the firewall.
- **sctp_association:** Defines the outgoing connection from the firewall to the final destination server (Osmocom STP) (192.168.56.30:8015).

Routing in the SS7 network is performed using Point Codes. A simple addressing scheme is defined for the lab: SigPloit (PC=1), SigFW (PC=2), and Osmocom STP (PC=3). These codes must be configured consistently across all devices.

4.3 Establishing and Verifying Connections

Services must be started in the correct order:

1. Osmocom STP,
2. SigFW,
3. SigPloit. To verify whether the connection is successful, the *sigfw.log* file, the management API (**https://192.168.56.20:8443/ss7fw_api/1.0/get_status**), and live packet analysis via Wireshark are monitored.

5. Offensive Operations and Firewall Verification

This section establishes the technical baseline for evaluating the firewall's detection posture by implementing standardized attack playbooks and advanced structural evasion methods.

5.1 Establishing and Verifying Connections

The GSMA FS.11 document, the industry standard guide for SS7 firewalls, categorizes threats into three main categories:

- **Category 1 (Prohibited Packets):** Messages that should never cross operator boundaries and are strictly internal.
- **Category 2 (Unauthorized Packets):** Messages that are contextually incorrect, such as cross-boundary requests for home network tracking data originating from unvouched sources.
- **Category 3 (Suspicious Location Packets):** Situations where legitimate message types are abused to execute tracking anomalies, such as geographically impossible velocities between consecutive location update requests.

Table 2: GSMA FS.11 Threat Categories and Corresponding MAP/CAMEL Messages

GSMA Category	Threat Description	Sample MAP/CAMEL Operation	Typical Filtering Logic
Category 1	Leakage of Internal Network Messages	ActivateTraceMode, PurgeMS	Block in all cases where the source network is not the local network.
Category 2	Location Spoofing/Unauthorized Information Request	UpdateLocation, ProvideSubscriberInfo (PSI)	Block if there is an inconsistency between the source GT address and the country to which the IMSI belongs.
Category 3	Impossible Speed Location Change	UpdateLocation	Block if the time and geographical distance between consecutive UpdateLocation messages indicate a physically impossible speed (Velocity Check).

The mathematical model underpinning the stateful Velocity Check tracking control is defined by a temporal and co-ordinate differential ratio: L1

$$V = \frac{\Delta d}{\Delta t}$$

Figure 3: Velocity check formula

Where Δd represents the spatial distance between the baseline location L_1 and the newly requested location $L2$ calculated over the earth's geodetic surface ($\Delta d = Distance(L1, L2)$), and Δt represents the temporal delta between the two inbound transactional timestamps $\Delta t = T2 - T1$). If $V > Vmax$, the packet is classified as an impossible travel anomaly and dropped.

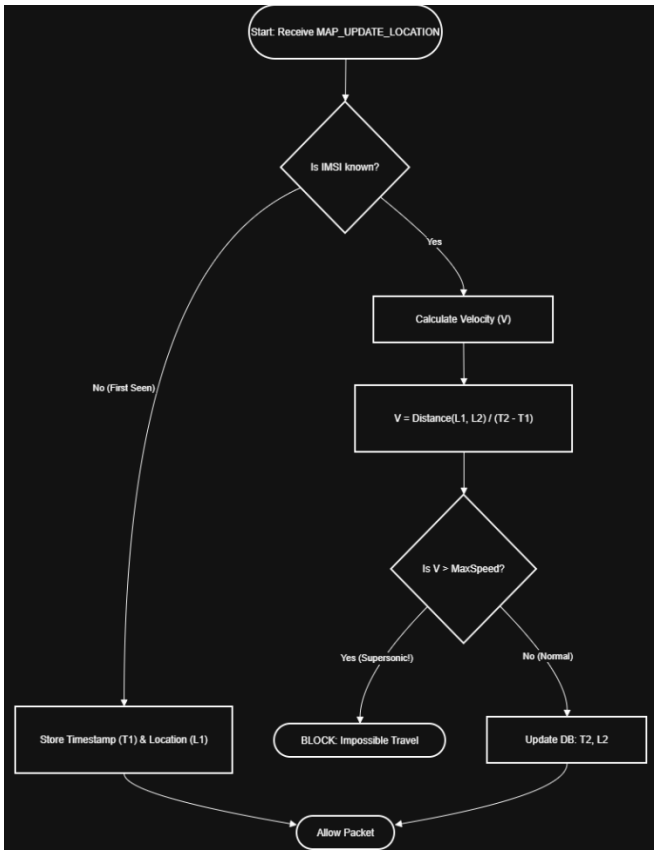

Figure 4: Logical flowchart illustrating the stateful Velocity Check verification algorithm applied to inbound Category 3 location update management

5.2 Execution of Standard Attacks and Advanced Evasion Techniques

To rigorously evaluate the framework, two distinct testing methodologies were executed: a firewall-enforced verification flight and a baseline validation flight where the firewall's filtering configurations were entirely bypassed to confirm that the attack tool (*SigPloit*) could achieve 100% exploit delivery directly to *Osmocom STP*.

During the firewall-active trials, a location tracking scenario was conducted by injecting a Category 2 ProvideSubscriberInfo (PSI) request (Operation Code 70) via SigPloit. The firewall rules were configured to validate incoming Calling Party Addresses (CgPA) at the SCCP layer against the targeted International Mobile Subscriber Identity (IMSI) blocks. Latency data was gathered by extracting the frame timestamp differentials between the firewall's inbound network interface and its outbound transit interface using automated PCAP post-analysis.

Following standard validation, parser difference attacks targeting structural decoding layers were introduced. This technique exploits intentional ambiguities in the Abstract Syntax Notation One - Basic Encoding Rules (ASN.1 BER) utilized by TCAP to establish transactions. A malformed packet was generated by writing a custom Python script to override standard length framing, explicitly utilizing an Indefinite Length descriptor for the IMSI parameter components inside the TCAP component portion.

The evaluation criteria defined a "Blocked" outcome as the firewall successfully generating an explicit rule drop log entry or issuing an SCTP Abort packet, whereas an "Allowed" outcome was marked if the packet was successfully replicated and pushed to the destination port of the target core server.

6. Firewall Activity Analysis and Reporting

This section compiles the empirical data gathered during testing, contrasting the behavioral results of rule-based enforcement against advanced protocol evasion.

6.1 Methodology for Security Assessment

A structured framework is used to present the findings of laboratory experiments. The key assessment criteria are as follows:

- Security Effectiveness: The ability to achieve True Positives (blocking malicious traffic) and True Negatives (forwarding valid packets).
- Performance Impact: The localized transactional delay (latency in milliseconds) introduced by deep packet inspection.
- Robustness: The systemic stability of the software stack when saturated with syntactically malformed streams.

6.2 Presentation of Findings: Test Matrix

The holistic behavior of the open-source firewall across the executed threat spectrum is documented below.

Table 3: Firewall Activity Test Matrix

Test ID	Description	Expected Result	Actual Result	Performance Impact (Latency - ms)	Evidence Reference (Log/PCAP)	Result (Pass/Fail)
TC-01	GSMA Layer 2: PSI Location Tracking	Blocked	Blocked	2 ms	sigfw.log:14:32:11, psi_blocked.pcap	Pass
TC-02	GSMA Layer 3: Velocity Check	Blocked	Allowed	1 ms	sigfw.log:14:38:20, velocity_allowed.pcap	Fail
TC-03	Legitimate Location Update (Check)	Allowed	Allowed	1 ms	legit_ul_allowed.pcap	Pass
TC-04	TCAP Avoidance: Malformed IMSI	Blocked	Allowed	2 ms	tcap_bypass.pcap	Fail
TC-05	Robustness: TCAP Fuzzing (10k packets)	No Crash	No Crash	5-10 ms	fuzzing_test.log	Pass

7. Conclusion

This laboratory study demonstrates the feasibility and technical value of constructing a high-fidelity SS7 signalling security research infrastructure using open-source utilities. The empirical data gathered from the test matrix indicates that while P1sec SigFW successfully thwarts basic, signature-reliant Category 2 tracking vectors (*TC-01*), it presents notable defensive shortfalls when challenged with complex threat models.

Specifically, the engine failed to enforce Category 3 rules due to the lack of an integrated state tracking database necessary for stateful velocity calculation (*TC-02*). More critically, the system proved susceptible to Parser Differential vulnerabilities (*TC-04*). When exposed to non-standard ASN.1 BER indefinite length structures, the firewall's Java-based decoder threw a parsing exception and defaulted to an insecure "Allow" state, while the target node successfully parsed and executed the nested payload.

These findings emphasize that securing legacy telecommunications infrastructure requires capabilities far beyond static signature matching. Future work will focus on expanding open-source testing tooling by engineering native TCAP/MAP dissection extensions for packet manipulation libraries and building specialized, open-source fuzzer frameworks to systematically validate the decoder robustness of core telecom switches.

Acknowledgements

The author wishes to express his deepest gratitude to his family and Elif Nurten for their unwavering support, continuous encouragement, and patience throughout the duration of this research project.

Ethics Declaration: This research did not require ethical approval as it involved the use of isolated laboratory environments and simulated network traffic using open-source tools, with no human participants or real-world subscriber data involved.

AI Declaration: Generative Artificial Intelligence (AI) tools have been used to assist with the translation and linguistic corrections of this article. The fundamental research, data analysis, and scientific findings are the author's original work.

Abstract: Cryptography plays a fundamental role in information security, being directly related to maintaining important properties such as confidentiality and integrity. Many of the algorithms that form the basis of cryptography are based on mathematically difficult computational problems, such as prime number factorization and discrete logarithm. However, the use of quantum computing algorithms poses a threat to some of these cryptographic systems, making communication systems and protocols that use them vulnerable. One example is Delay-Tolerant Networks (DTNs), which have high applicability in space systems and military contexts, but present challenging characteristics for secure implementation. One initiative to combat this threat is the development of algorithms resistant to quantum attacks, collectively known as post-quantum cryptography. These algorithms are based on other mathematical classes that do not have a known optimized solution for quantum or classical computers, but, on the other hand, present greater computational, storage, and data transmission demands. Due to these characteristics, their use must be evaluated according to the context, considering the degree of security required in conjunction with processing, memory, and routing limitations. Thus, this work aimed to conduct a survey of the main characteristics and challenges of cryptographic systems to counter quantum cryptanalysis, paying special attention to the post-quantum algorithm Module-Lattice Key-Encapsulation Mechanism (ML-KEM), as well as its vulnerabilities to hardware-level implementation attacks and spaceborne radiation environments. Furthermore, the main architectural characteristics of DTNs were presented, and security aspects and challenges described in the Bundle Protocol Security (BPSec)—specifically regarding the amplification of message-flooding vulnerabilities under expanded post-quantum payloads—were addressed. Finally, suggestions for future work were presented based on opportunities identified throughout the study.

Keywords: Quantum computing, Delay-tolerant networks, Post-quantum cryptography, Bundle protocol

1. Introduction

The use of cryptography is fundamental for information security, contributing to systems that transmit, store, or manipulate data achieving fundamental characteristics like confidentiality and integrity, in addition to others such as authentication. Such systems vary widely according to criteria such as computational power and data transfer through computer networks. These characteristics can impose additional restrictions on the use of cryptography, such as delay-tolerant or disruption-tolerant networks (DTN), designed for delayed/disrupted connectivity environments.

On the other hand, attacks on encryption systems known as cryptanalysis can lead to the compromise of an algorithm's key, and consequently the data of those who use it. For example, the Data Encryption Standard (DES) was a symmetric encryption standard that, after years of use, became vulnerable due to the increase in computational power available for cryptanalysis. This led to the development of a new, more computationally expensive symmetric cryptographic standard, the Advanced Encryption Standard (AES).

However, new attacks are constantly being developed, making use of new algorithms and increased computing power, such as the latest quantum cryptanalysis algorithms. This new threat has led to the need to develop new cryptographic algorithms, which gave rise to post-quantum cryptography. These algorithms, however, may require greater computational power and a larger volume of stored and transmitted cryptographic data, which poses an additional challenge for DTN networks.

Therefore, researchers must analyze the use of schemes that allow for the secure establishment of keys, while simultaneously meeting the constraints of the systems in which they will be applied. To understand the need for post-quantum cryptography in military and satellite DTN networks, this study first evaluates the imminent threats posed by quantum cryptanalysis.

2. Quantum Cryptanalysis

2.1 Grover's Algorithm and its Impact on Symmetric Cryptography and Hashing

Grover's algorithm is a quantum algorithm for searching unstructured databases, such as an unordered vector of numerical data. The algorithm offers a quadratic speedup compared to classical methods, that is, while a classical computer requires on the order of N evaluations to find an item in a space of N elements in the worst case, Grover's algorithm requires only $N^{0.5}$ operations (Preston, 2023).

This result has direct implications for AES. Because of it, systems need to use at least AES-256 (32 bytes, of 256 bits, key) to remain resistant to Grover's algorithm (Rao et al., 2017). Hash functions are also targeted by the algorithm, making the use of SHA-256 necessary to resist quantum cryptanalysis (Preston, 2023).

2.2 Shor's Algorithm: History and Implementation Challenges

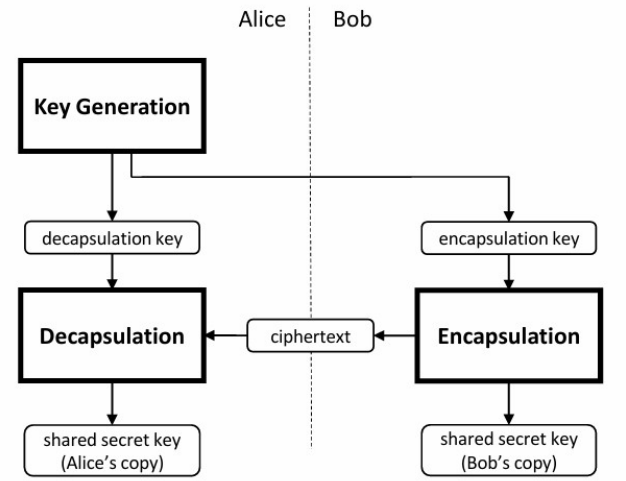
Another quantum algorithm applicable to cryptanalysis was proposed by Peter Shor in 1994. This algorithm solves integer factorization and discrete logarithm problems in polynomial time, offering an exponential speedup over the best-known classical algorithms, such as the Number Field Sieve (Shor, 1997). Also, theoretical improvements have been proposed, such as Regev's algorithm, which reduces the number of quantum gates required to $O(n^{3/2})$ (Regev, 2025). Such results directly compromise widely used public-key cryptosystems, including RSA and Elliptic Curve Cryptography (ECC) (Rao et al., 2017).

The practical implementation of Shor's algorithm, however, faces significant physical challenges, mainly related to quantum decoherence—the loss of coherence due to the interaction of the system with the environment (Chuang et al., 1995). Historically, experimental demonstrations have been limited to small numbers due to the requirement for precise control over the qubits.

One of the first notable implementations occurred in 2001, using Nuclear Magnetic Resonance (NMR) to factor the number 15 using 7 qubits. Although successful, the experiment highlighted the difficulty of scalability due to decoherence and the complexity of spin coupling networks (Vandersypen et al., 2001).

To overcome resource limitations, later approaches focused on circuit optimization. In 2012, a photonic implementation factored the number 21 using a "qubit recycling" technique. This iterative version of the algorithm replaces the n-qubit control register with a single qubit reused n times, reducing the total resource demand to about one-third of the standard protocol, demonstrating a viable path to scalability (Martín-López et al., 2012).

More recently, hybrid approaches such as Variational Quantum Factoring (VQF) have been tested on superconducting processors. Experiments factoring larger numbers have revealed that, in addition to traditional decoherence, coherent errors represent dominant barriers to the successful execution of quantum optimization algorithms (Karamlou et al., 2021).



Although implementing the Shor's algorithm is still a challenge, continuous progress has been made, leading to the need to seek new cryptographic solutions to prevent the compromise of information security.

3. Module-lattice Key-encapsulation Mechanism

To counter the previously mentioned quantum cryptanalysis algorithms, one approach involved developing a new class of classical cryptographic algorithms, collectively known as post-quantum cryptography (Bavdekar et al., 2023). Although other methods have been studied (Bavdekar et al., 2023), lattice-based cryptography has been standardized by NIST for use in key establishment and also in digital signatures (NIST, 2024a, 2024b). Lattices are algebraic structures where certain computational problems, such as the Module Learning With Errors (MLWE) problem, are believed to be intractable for both classical and quantum computers.

For key establishment, the first chosen algorithm was the Module-Lattice-Based Key-Encapsulation Mechanism (ML-KEM). ML-KEM consists of three fundamental operations (Alagic et al., 2025), which are also represented in the scheme in Figure 1:

- Key Generation: a pair of encapsulation/decapsulation keys is generated by one party (Alice), and the encapsulation key is sent to the other party (Bob);
- Encapsulation: after receiving the encapsulation key, Bob performs an operation that generates the shared secret in both plaintext and ciphertext form, which is then sent to Alice; and
- Decapsulation: Alice receives the ciphertext and uses her key to decrypt the shared secret.

Note. Source: Alagic et al. (2025)

Figure 1: ML-KEM overview

The process described above can occur in two distinct ways, ephemeral or static. In the first, for each generation of a shared secret, the entire process must be performed, and the generated keys must be discarded after use. In the second, the key generation is done once, and the encapsulation key is distributed to all parties who wish to generate a shared secret. It should be noted that the generated secrets are distinct from each other (Alagic et al., 2025).

The proponents of the algorithm specified three sets of parameters: ML-KEM-512, ML-KEM-768, and ML-KEM-1024, targeting security categories 1, 3, and 5, respectively. Table 1 shows the size values for the three configurations.

Table 1: ML-KEM settings (values in bytes)

Algorithm	Encapsulation key	Decapsulation key	Ciphertext	Secret key
ML-KEM-512	800	1632	768	32
ML-KEM-768	1184	2400	1088	32
ML-KEM-1024	1568	3168	1568	32

Note. Source: NIST (2024)

Regarding practical deployment, ML-KEM demonstrates high versatility and can be implemented across diverse software and hardware architectures, including central processing units (CPUs), graphics processing units (GPUs), application-specific integrated circuits (ASICs), and field-programmable gate arrays (FPGAs) (Nguyen et al., 2025). This adaptability extends to extreme operational environments such as space systems, where the algorithm has proven viable on radiation-hardened FPGAs and embedded space-grade processors (Kim, 2026).

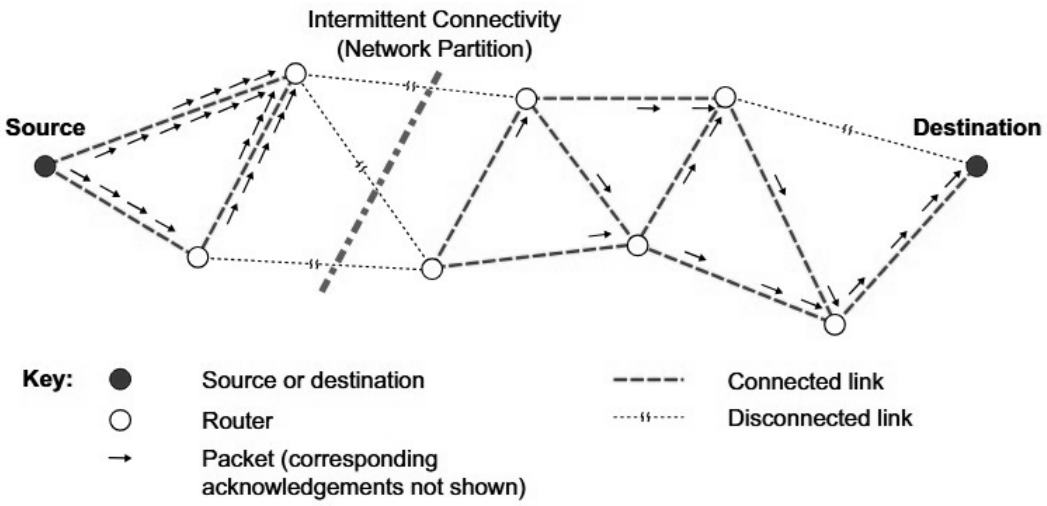
However, deployment in these specialized environments is bounded by severe physical and hardware constraints that mandate careful resource optimization (Kim, 2026; Nguyen et al., 2025). Most critically, spaceborne implementations are generally prohibited from utilizing standard external DDR memory due to its susceptibility to radiation-induced single-event upsets (SEUs), forcing the cryptographic subsystem to rely entirely on severely limited on-chip static memory (Kim, 2026). Furthermore, these systems must operate within strict power budgets while handling the transmission of larger post-quantum keys over highly constrained telemetry bandwidths (Kim, 2026).

The security of ML-KEM against both classical and quantum computing adversaries is fundamentally derived from the hardness of the MLWE problem, which establishes a baseline security of indistinguishability under chosen-plaintext attack (IND-CPA) (Avanzi et al., 2021). According to the NIST evaluation criteria, this passive IND-CPA security framework is considered sufficient for purely ephemeral key exchange protocols, (NIST, 2016). For the static deployments, the scheme applies a Fujisaki-Okamoto (FO) transform to the underlying IND-CPA-secure encryption to achieve the required indistinguishability under adaptive chosen-ciphertext attacks (IND-CCA2) (Avanzi et al., 2021).

Despite its robust mathematical foundations, practical deployments of ML-KEM remain susceptible to physical hardware exploits, which is a critical consideration for exposed nodes in Delay Tolerant Networks (Nguyen et al., 2025; Renita et al., 2025). These physical vulnerabilities bypass theoretical protections and are predominantly divided into passive Side-Channel Attacks (SCA) and active Fault Injection Attacks (FIA) (Ravi et al., 2024).

Passive SCAs exploit unintentional physical leakages, such as power consumption and electromagnetic (EM) emanations (Renita et al., 2025). The decapsulation phase is particularly vulnerable; attackers can utilize Deep Learning-enhanced Side-Channel Analysis (DL-SCA) to extract secret polynomial coefficients during Number Theoretic Transform (NTT) or point-wise multiplication operations (Hoang et al., 2024; Renita et al., 2025). This technique is highly efficient, requiring as few as 50 traces, and can successfully compromise even hardware implementations that use parallel architectures (Hoang et al., 2024). By exploiting these leakages, adversaries can construct practical plaintext-checking or decryption-failure oracles to systematically recover the secret key (Ravi et al., 2024).

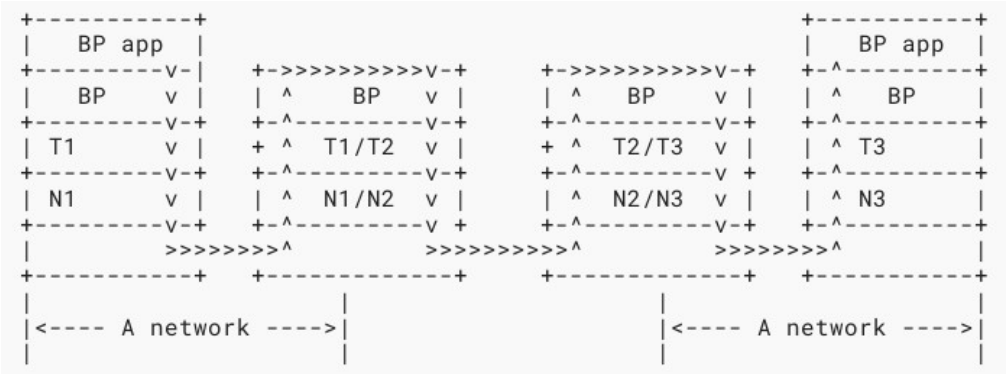
In addition to power and EM leakages, ML-KEM is threatened by timing-based vulnerabilities, notably the KyberSlash exploits (Bernstein et al., 2024; Ji et al., 2025). These vulnerabilities occur when compilers optimizing for code size inadvertently introduce variable-time division operations during ciphertext compression or message decoding (Bernstein et al., 2024). Because the execution time of these operations depends on the secret inputs, they reliably leak key information, allowing systems to be compromised remotely or without advanced physical measurement probes (Bernstein et al., 2024).



Finally, ML-KEM is also threatened by active manipulation through Fault Injection Attacks (FIA), which deliberately induce transient hardware errors (Renita et al., 2025). Advanced FIA techniques include loop-abort faults induced via electromagnetic pulses, which target the standardized KECCAK hash function across all operational phases (Wang et al., 2025). These faults allow adversaries to bypass permutations or zeroize crucial arrays to effortlessly recover secret random seeds (Wang et al., 2025). Other critical fault vectors include corrupting NTT twiddle factors, forcing nonce reuse during the sampling of ephemeral secrets, or using clock glitching to completely skip the final ciphertext equality check—effectively downgrading the protocol to weaker indistinguishability under chosen-plaintext attack (IND-CPA) security (Ravi et al., 2024; Ji et al., 2025).

4. Delay/Disruption Tolerant Networks

Delay-Tolerant and Disruption-Tolerant Networks (DTNs) are designed to operate in contexts where the use of the traditional TCP/IP protocol stack presents limitations, such as high error rates, delays that can reach the order of days, and lack of end-to-end connectivity (Cerf et al., 2007; Gao et al., 2015). DTNs can be applied in scenarios such as underwater networks, satellite networks, sensor networks, or battlefield networks (Cerf et al., 2007; Gao et al., 2015). Bravo et al. (2025) analyzed the use of LunaNet, which uses the DTN architecture, on the International Space Station for a period of eighteen days, conducting a series of experiments to verify its behavior and performance (Bravo et al., 2025). The characteristics of DTNs are also being integrated into vehicular network projects, Vehicular-DTN (Pereira, 2011). Some studies have also been conducted on the application of DTNs in rural areas (Abdeljabar et al., 2025; Hanifah et al., 2025).



A disruption scenario is represented in Figure 2, where the network becomes partitioned, preventing the routing of packets between the source and destination. To address the problem of lack of connectivity and high error rates, the nodes belonging to DTNs use a store-and-forward approach in which packets are stored so that they can be transmitted when the link is re-established (Cerf et al., 2007).

DTNs utilize the Bundle Protocol (BP), where the term "bundle" refers to the packet used. BP acts as an overlay layer over other network and transport protocol stacks, called Convergence Layers, allowing different networks to be interconnected (Burleigh et al., 2022). Figure 3 shows a DTN formed by two different networks connected so that BP applications (BP app) can exchange messages. The variety of Convergence Layers is represented by the pairs Tx/Nx, with x varying from 1 to 3.

Note. Source: Burleigh et al. (2022)

Figure 3: Overlay BP with different stack convergence layers

Security in DTN networks is provided by the Bundle Protocol Security (BPSec) protocol, defined in RFC 9172. BPSec was designed to operate independently of the network topology, applying security services directly to the data, rather than protecting the communication channel, since end-to-end connectivity is not guaranteed (Birrane & McKeever, 2022). The protocol does not impose fixed cryptographic algorithms; instead, it uses context identifiers to abstract the cipher suite and parameters used (Birrane et al., 2023).

The introduction of post-quantum algorithms imposes additional challenges on key management, mainly due to the larger size of keys and signatures. BPSec facilitates this transition by allowing additional security parameters (such as encapsulated keys or salts) to be transported within the security blocks themselves (Birrane et al., 2023). Key management must consider that, in a DTN, a key valid at the time of sending may have expired by the time of reception, requiring security policies that take network latency into account. Not only that, but one must also consider the challenge of distributing keys in an environment where there may not be end-to-end connectivity for the execution of the protocols (Birrane et al., 2023).

Building on these connectivity challenges, the store-carry-and-forward paradigm uniquely exposes Delay Tolerant Networks (DTNs) to a range of operational threats. Because DTNs strictly require cooperation between intermittent nodes to deliver messages, they are highly susceptible to routing misbehavior (Nabais et al., 2021). The most critical threats include Black-hole attacks, where compromised nodes silently drop received messages instead of forwarding them, and Wormhole attacks, where adversaries tunnel packets through hidden, low-latency links to manipulate the perceived network topology (Altaweel et al., 2023; Nabais et al., 2021). Additionally, attackers may launch Sybil attacks by forging or stealing multiple identities to aggressively influence routing decisions and intercept traffic, exploiting the fundamental nature of opportunistic contacts to disrupt the network (Altaweel et al., 2023).

Furthermore, the resource constraints of DTN nodes make them prime targets for Denial-of-Service (DoS) and Distributed DoS (DDoS) attacks (Khalid et al., 2023; Zekkori et al., 2021). Adversaries may deploy flooding attacks, overwhelming the network with genuine, replicated, or entirely forged bundles to rapidly deplete node buffers and congest available wireless bandwidth (Khalid et al., 2023; Zekkori et al., 2021). In environments like space information networks, where components are physically inaccessible and structurally constrained, these resource-exhaustion attacks can be catastrophic. By forcing legitimate nodes to drop crucial packets due to buffer overflow, flooding halts communication and critically degrades the network's packet delivery ratio (Sharmin et al., 2025; Zekkori et al., 2021).

5. SWOT Analysis

5.1 Strengths

- Robust Quantum Resistance: ML-KEM utilizes the Fujisaki-Okamoto (FO) transform to provide strong indistinguishability under adaptive chosen-ciphertext attacks (IND-CCA2), ensuring that data remains secure against both classical and future quantum adversaries.
- Computational Efficiency: Compared to other post-quantum algorithms, ML-KEM is efficient for memory and processing-constrained environments because it leverages the Number Theoretic Transform to optimize polynomial multiplications with minimal resource overhead.
- Protocol Adaptability: The Bundle Protocol Security standard utilized in DTNs allows the integration of post-quantum cryptography without requiring fundamental architectural changes.

5.2 Weaknesses

- Resource Overhead: ML-KEM demands significantly larger key and ciphertext sizes compared to classical cryptography; for instance, ML-KEM-768 requires an 1184-byte encapsulation key and a 1088-byte ciphertext. This heavy data footprint might conflict with the buffer constraints of DTN nodes.
- Synchronous Assumptions in Asynchronous Networks: ML-KEM key exchange assumes prompt communication, which is not always possible in DTNs. A post-quantum key valid at the time of transmission may expire before reaching its destination, complicating key management.

5.3 Opportunities

- Environmental Immunity to Implementation Attacks: Assuming the nodes are physically inaccessible (e.g., satellites), it’s practically impossible for adversaries to attach measurement probes or use electromagnetic equipment to launch passive Side-Channel Attacks or active Fault Injection Attacks. Furthermore, the extreme latency and frequent disruptions inherent to the DTN architecture completely mask the minute clock-cycle variations required to execute remote timing attacks, rendering vulnerabilities like the KyberSlash exploits ineffective.
- Specialized Hardware Integration: Advances in space-grade Field-Programmable Gate Arrays (FPGAs) allow ML-KEM to be implemented efficiently using entirely on-chip static memory, avoiding the need for external DDR memory.

5.4 Threats

- Amplification of Flooding Attacks: Because DTNs are highly susceptible to DoS and flooding attacks, the substantially larger payload of ML-KEM keys and ciphertexts makes it much easier for remote adversaries to rapidly exhaust node buffers and wireless bandwidth.
- Environmental Faults: Even without physical access by a human attacker, space-based DTN nodes are constantly bombarded by galactic cosmic rays and radiation. This environment induces Single-Event Upsets —random bit flips in memory that can corrupt keys or intermediate computations, effectively mirroring the disruption of a malicious Fault Injection Attack. This threat is particularly acute for ML-KEM, because its expansive public key and ciphertext sizes present a vastly larger operational memory profile than classical cryptography, reducing the mathematical probability of error-free state retention across the system.

6. Future Work

Based on the topic discussed and the SWOT analysis, three recommendations for future work involving the use of post-quantum cryptography in systems connected to DTNs are presented.

- Investigate decentralized, latency-aware key management policies for ML-KEM in DTNs. Future studies must specifically address the 'Synchronous Assumptions' weakness by exploring how to handle key expiration, asynchronous certificate revocation, and delayed authentication in an environment where a post-quantum key may expire before reaching its destination;
- Evaluate the performance impact of ML-KEM's large cryptographic payloads on various DTN routing protocols. Because the substantial size of post-quantum keys exacerbates the network's susceptibility to resource-exhaustion and flooding attacks, future research should investigate lightweight, randomized routing algorithms (such as k-RAND) or anomaly detection mechanisms to dynamically protect node buffers from being overwhelmed by cryptographic traffic; and
- Explore the hardware-software co-design of Hardware Security Modules (HSMs) optimized for post-quantum cryptography in space systems. Future work should focus on implementing ML-KEM within the strict confines of on-chip static memory (avoiding DDR), while developing fault-tolerant architectures to mitigate Single-Event Upsets (SEUs) from cosmic radiation, which can fatally corrupt keys and mirror malicious Fault Injection Attacks.

7. Conclusion

The imminent threat of quantum computing requires a shift towards post-quantum cryptography to ensure long-term security. This work explored this transition, focusing on the Modular Lattice-Based Key Encapsulation Mechanism (ML-KEM) and the dynamics of deploying it within Delay-Tolerant Networks (DTNs) for space systems.

While ML-KEM is theoretically robust, practical deployments are susceptible to physical hardware exploits, such as passive Side-Channel Attacks (SCA), active Fault Injection Attacks (FIA), and remote timing vulnerabilities like KyberSlash. However, the unique environmental characteristics of DTNs actually provide a natural defense against these threats. For physically inaccessible DTN nodes like satellites, it is practically impossible for adversaries to attach measurement probes required to launch local SCAs or FIAs. Furthermore, the extreme latency and frequent disruptions inherent to the DTN architecture completely mask the minute clock-cycle variations necessary to execute remote timing attacks, rendering vulnerabilities like KyberSlash ineffective.

Despite this environmental immunity to certain implementation attacks, significant challenges remain. The substantial resource overhead of ML-KEM, specifically its larger key and ciphertext sizes, amplifies existing network-level vulnerabilities in DTNs. This heavy data footprint makes constrained nodes much more susceptible to resource-exhaustion and flooding attacks. Additionally, space-based DTNs must contend with radiation-induced single-event upsets (SEUs) which corrupt keys and intermediate computations, effectively mirroring the disruption of malicious fault injections without requiring a human attacker.

Addressing these challenges will require investigating decentralized, latency-aware key management policies, developing lightweight routing algorithms to protect against payload-amplified flooding, and exploring fault-tolerant co-designs to mitigate radiation hazards in space systems.

Ethics Declaration: Ethical clearance was not required for this research, as the study involves a survey of existing literature and does not involve human participants, animal subjects, or the collection of sensitive personal data.

AI Declaration: Google NotebookLM was utilized during the development of this paper as a tool for self-study and to enhance the comprehension of the technical concepts.

Investigating AI Enabled Attacks and Malware Within Dark Web Ecosystems: An Updated Assessment

Chuck Easttom and William Butler
Vanderbilt University and Georgetown University; Washington, USA

chuckeasttom@gmail.com
whbutler@captechu.edu

Abstract: This paper provides a technically grounded assessment of how Dark Web ecosystems are intersecting with AI-enabled offensive cyber capabilities to compress time-to-effect across the cyber kill chain. Hidden-service marketplaces and broker forums have matured into resilient, quasi-industrial supply chains for initial access vectors (credential dumps, VPN/RDP footholds), exploit artifacts, malware loaders, and operational services (bulletproof hosting, cryptomixers, DDoS booter capacity). Generative AI and machine-learning–assisted tooling increases attacker throughput by automating target enumeration, vulnerability triage, exploit parameterization, and social-engineering content generation, thereby reducing the marginal cost of tailored intrusion campaigns. We synthesize research on anonymity architectures, dark-market economics, and emerging autonomous cyber systems to characterize an operational model in which AI agents execute multi-step workflows: (i) harvesting and fusing threat-intelligence signals from forum discourse and market telemetry; (ii) selecting targets via probabilistic scoring informed by asset criticality and exploitability; (iii) generating polymorphic payload variants and adversarial phishing lures; and (iv) iterating tactics in response to defensive controls through reinforcement-learning–style feedback. This convergence enables hybrid state–criminal collaboration and proxy operations by decoupling capability acquisition from attribution and by supporting deniable command-and-control (C2) staging within onion-routed infrastructures. Quantitative telemetry underscores the strategic relevance of this shift: the FBI's IC3 reported losses exceeding US$16 billion in 2024, with cyber-enabled fraud comprising approximately US$13.7 billion and 'cyberthreats' (including ransomware and data breaches) contributing more than US$1.5 billion, illustrating the scale of the economic attack surface. In parallel, breach forensics continue to show that initial access is frequently achieved through stolen credentials, vulnerability exploitation and social engineering, which are precisely the phases most susceptible to AI-driven acceleration. We conclude that AI-augmented Dark Web ecosystems materially increase campaign scalability, complicate attribution via supply-chain opacity and pseudonymity, and elevate escalation risk by enabling rapid re-tooling and persistent access. The paper closes with engineering-oriented defensive implications, including telemetry-driven detection, graph-analytic threat-hunting, and governance controls for AI-enabled offensive automation.

Keywords: Dark web, TOR, Cyber warfare, Cyber operations

1. Introduction

Cyber warfare continues to evolve as states and non-state actors exploit anonymity, deniability, and persistent access. The Dark Web sits at the center of this environment, functioning as both an illicit marketplace and an operational layer for covert activity. Foundational work on onion routing and anonymity architectures (Goldschlag, Reed, & Syverson, 1999; Reed, Syverson, & Goldschlag, 1998; Syverson, Goldschlag, & Reed, 1997) established the technical basis for the hidden-service ecosystems that now support cyber operations. Subsequent research has documented how Dark Web markets facilitate illicit trade, criminal collaboration, and the diffusion of offensive capabilities (Meehan & Farmer, 2023; Broséus et al., 2016; Buxton & Bingham, 2015; Kruithof et al., 2016). These ecosystems have also been repeatedly linked to child exploitation networks, access-broker activity, and large-scale takedowns such as AlphaBay and Playpen (Cimpanu, 2016; FBI, 2017; McGoogan, 2017; Popper & Ruiz, 2017). As cyber conflict has matured into a recognized operational domain (Nichols, 2024), the Dark Web has become a strategic substrate for procurement, coordination, and covert communication.

Concurrently, the operational environment surrounding offensive cyber activity is shifting as generative AI becomes embedded in the tooling and tradecraft of modern threat actors. Research on AI-enabled cyber operations shows that these systems amplify existing offensive techniques by accelerating reconnaissance, refining target selection, and automating technically demanding tasks (Gabrian, 2024; Saade & Ng, 2024). RAND's analysis of autonomy, reasoning, and tool-integration suggests that emerging AI systems may increasingly support multi-step cyber activities and adapt to defensive measures in real time (Hodgson, Horton, & Malone, 2025). When paired with the anonymity, resilience, and illicit economies of the Dark Web, these AI-driven capabilities create a more fluid and adaptive threat landscape to one where state and non-state actors can blend, outsource, and obscure their operations with unprecedented ease. This convergence is becoming a defining feature of contemporary cyber conflict and a critical factor in understanding how offensive capabilities are acquired, deployed, and sustained.

2. Cryptographic Foundations: Onion Routing and Anonymity Architecture

The following sections provide a technical overview of onion routing and associated technologies.

2.1 Onion Routing Protocol Design

Onion routing is a layered cryptographic forwarding architecture designed to decouple message origin, routing state, and destination information across multiple independently operated network relays. In this model, a client encapsulates application traffic inside a sequence of encrypted protocol layers, where each layer corresponds to a specific relay in a selected path, conceptually resembling the nested structure of an onion (Reed, Syverson, & Goldschlag, 1998). In Tor, this path is instantiated as a circuit, usually consisting of an entry guard, one or more middle relays, and an exit relay. Before user traffic is transmitted, the Tor client performs circuit construction by incrementally extending the circuit one hop at a time. For each hop, the client negotiates a distinct ephemeral session key, historically using telescoping key agreement protocols based on public-key cryptography and, in modern Tor deployments, authenticated key exchange mechanisms that provide forward secrecy. These per-hop session keys are then used with symmetric cryptographic primitives to encrypt fixed-size Tor cells in multiple layers.

At the protocol level, the client does not simply send an IP packet through the relay chain. Instead, it fragments traffic into Tor cells, each of which contains circuit identifiers, relay commands, stream identifiers, integrity checks, and encrypted payload data (Döpmann, 2025). When the client sends a cell into the circuit, it applies layered encryption in reverse path order: first encrypting the payload for the exit relay, then wrapping that ciphertext for the middle relay, and finally encrypting the outermost layer for the entry relay. As the cell traverses the circuit, each relay uses only its own negotiated symmetric key to remove one cryptographic layer, verify the relevant integrity material, and determine the next hop. Crucially, a relay learns only the routing information necessary for local forwarding. It does not possess the cryptographic keys required to decrypt layers intended for other relays, nor does it receive a complete source-to-destination route.

This design produces strict compartmentalization of network visibility (Dutta et al., 2021). The entry guard observes the client's network address and the next relay in the circuit, but it cannot determine the final destination or inspect application-layer plaintext. The middle relay functions as a cryptographic and routing intermediary, observing only its predecessor and successor within the circuit (Döpmann, 2025). The exit relay removes the final Tor encryption layer and forwards traffic to the destination service, meaning it can observe the destination address and, unless end-to-end encryption such as TLS is used, potentially the application payload; however, it does not know the client's original IP address. Thus, anonymity is not derived from any single trusted server, but from distributing trust across relays and ensuring that no individual relay has sufficient information to correlate both communication endpoints.

The security properties of onion routing rely on the interaction between layered symmetric encryption, ephemeral key establishment, circuit isolation, and probabilistic relay selection (Döpmann, 2025). Public-key cryptography is used primarily during circuit setup to authenticate or establish shared secrets, while high-throughput data forwarding is handled by efficient symmetric encryption because relays must process large volumes of traffic with low latency (Camenisch, J., & Lysyanskaya, 2005). Ephemeral session keys provide forward secrecy: compromise of a relay's long-term identity key should not automatically reveal previously transmitted circuit traffic. Tor's use of fixed-size cells also reduces certain packet-size leakage, although it does not eliminate timing correlation attacks. Because low-latency anonymity systems must preserve interactivity, Tor cannot fully randomize packet timing or introduce large delays in the way high-latency mix networks do.

Path selection further contributes to anonymity by drawing relays from a distributed consensus of available nodes, weighted by relay capacity, policy constraints, and role suitability. Entry guards are typically reused for extended periods to reduce exposure to malicious first-hop relays, while middle and exit relays may vary across circuits. Exit relay selection is constrained by exit policies, since not all relays permit outbound connections to all ports or destinations (Camenisch, J., & Lysyanskaya, 2005). The resulting anonymity set depends on the number of users, the diversity of relay operators, relay bandwidth distribution, and the adversary's ability to observe or operate relays. If a global passive adversary can monitor both the client-to-entry link and the exit-to-destination link, traffic timing and volume correlation may still weaken anonymity despite the cryptographic protections.

Recent analyses of AI-enabled cyber operations highlight how adversaries increasingly pair traditional anonymity architectures with AI-driven reconnaissance and automation tools to streamline circuit construction, evade detection, and optimize routing behavior (Gabrian, 2024). RAND's assessment of autonomy and tool-integration

further suggests that future AI systems may assume more active roles in route selection, traffic shaping, and relay-level evasion, enhancing the operational resilience of onion-routed communications (Hodgson, Horton, & Malone, 2025). These developments indicate that while the core cryptographic design remains stable, the operational use of onion routing is evolving alongside AI-enabled offensive tradecraft

2.2 Traffic Analysis and Limitations

While onion routing provides strong resistance to single-point compromise, it is not invulnerable. Adversaries capable of large-scale traffic correlation monitoring both entry and exit nodes can conduct timing analysis to probabilistically deanonymize users (McCoy et al., 2008; Nurmi & Niemelä, 2017). Intelligence agencies have historically bypassed Tor's cryptographic protections through network investigative techniques (NITs), browser exploits, and endpoint compromise, demonstrating that anonymity networks protect routing metadata but not the security posture of the device itself (Paganini, 2015; Schneier, 2013). AI-enabled tooling is intensifying these risks. Gabrian (2024) notes that machine-learning models now accelerate traffic-pattern recognition and automate correlation attacks, identifying subtle timing or volume anomalies that human analysts might overlook.

RAND's assessment reinforces this trajectory, emphasizing that as AI systems gain more advanced reasoning and tool-integration capabilities, they may increasingly support multi-step offensive actions including reconnaissance, exploitation, and traffic analysis—within anonymized environments (Hodgson, Horton, & Malone, 2025). These developments suggest that the threat surface surrounding onion-routed traffic is evolving not because the cryptographic design has weakened, but because adversaries now possess more capable analytical tools. Despite these vulnerabilities, Tor's architecture remains sufficiently robust to provide operational-grade anonymity for actors who combine it with disciplined OPSEC practices such as compartmentalization, cryptocurrency obfuscation, and endpoint hardening.

3. How the Dark Web is Used in Cyber Warfare

Style and Maglaras (2020) define cyber warfare as the use of digital operations to target states or non-governmental entities, noting that virtual actions can produce tangible physical effects. Boyte et al. (2020) demonstrate this reality through cyberattacks on Ukraine from 2013–2015 that disrupted power grids, satellite communications, and weapons systems. Recent analyses further show that generative AI is accelerating offensive capability development by enhancing reconnaissance, vulnerability discovery, and malware adaptation, expanding the operational reach of cyber actors (Gabrian, 2024; Hodgson, Horton, & Malone, 2025).

Dark web marketplaces operate as semi-structured ecosystems for acquiring malware, zero-day exploits, and access credentials outside formal state channels (Hasanti et al., 2024). Reputation systems and escrow mechanisms help sustain trust in an anonymous environment, lowering the technical and economic barriers to sophisticated cyber tools. This commodification accelerates the proliferation of offensive capabilities once limited to nation-states, enabling both state and non-state actors to adopt advanced techniques more rapidly (Pavlovskaia & Belousov, 2024). The dark web also supports recruitment and coordination through anonymity-preserving architectures and global accessibility. State-linked groups and independent contractors advertise services, solicit collaborators, and form loosely organized collectives oriented toward political or financial objectives. This decentralized model complicates attribution, distributing operational tasks across actors with diverse motivations and producing hybrid campaigns that blur the line between state operations and criminal entrepreneurship.

Adversaries further leverage Dark Web hidden services to establish resilient command-and-control infrastructures (Gaber & Ahmed, 2026). Layered encryption and pseudonymous routing obscure server locations and operator identities, enhancing operational survivability. By decoupling C2 infrastructure from conventional hosting, Dark Web based architectures reduce the effectiveness of takedown efforts and complicate forensic analysis, contributing to the persistence and stealth of modern malware campaigns.

The Dark Web also serves as a repository of illicit data and cyber-threat intelligence (Kühn, Wittorf, & Reuter, 2024). Actors obtain compromised credentials, network access, and proprietary information that facilitate initial intrusion or accelerate reconnaissance. Monitoring dark web forums reveals emerging vulnerabilities, criminal collaborations, and evolving attack methodologies, complementing traditional intelligence collection and supporting long-term infiltration strategies used by state-sponsored APT groups. In information warfare, the Dark Web functions as a staging ground for disinformation and psychological operations. Its anonymous infrastructure enables the distribution of leaked or fabricated materials, coordination of influence networks, and propagation of ideologically charged narratives without clear attribution. Because these activities often migrate

to mainstream platforms, Dark Web operations can exert disproportionate influence, illustrating the convergence of cyber and cognitive warfare.

Cryptocurrency based financial systems embedded within the Dark Web provide the economic substrate for illicit cyber operations (Jung et al., 2022). Anonymous payments support malware procurement, infrastructure leasing, and contractor labor, while laundering mechanisms obscure transactional provenance. This financial opacity enhances the strategic autonomy of state and non-state actors engaged in cyber warfare and frustrates counter-financial intelligence efforts. The Dark Web mediates complex interactions between state actors and criminal organizations, fostering hybrid ecosystems where capabilities, intelligence, and operational services are exchanged with minimal visibility. States may outsource cyber activities to criminal proxies to achieve plausible deniability, while criminal groups may receive protection or technical support in exchange for aligning their operations with state interests. Cyber terrorism encompasses terrorist activity conducted through digital networks, including system attacks, online propaganda, psychological operations, fundraising, recruitment, and operational coordination (Lucas, 2020).

4. The Nexus of AI, Dark Web, and Cyber Warfare

The integration of Artificial Intelligence (AI) into Dark Web ecosystems has reshaped the operational landscape of cyber warfare by enabling autonomous, adaptive, and scalable capabilities under conditions of strong anonymity and reduced attribution (Kela, 2025). Within Tor and mix-net infrastructures, AI-driven systems support automated reconnaissance, threat-intelligence generation, and offensive cyber operations. Machine-learning model, ranging from supervised classifiers to deep neural networks, analyze Dark Web traffic, forum communications, and marketplace telemetry to identify vulnerabilities, zero-day opportunities, and adversarial behavioral patterns. Transformer-based NLP enables automated extraction of intent, ideological alignment, and operational indicators from unstructured extremist discourse, supporting cyber-enabled psychological operations and coordinated attack planning. These capabilities allow state and non-state actors to execute AI-augmented campaigns that dynamically adapt malware payloads, C2 structures, and attack vectors in response to defensive countermeasures, compressing the cyber kill chain. Gabrian (2024) underscores this shift, noting the widespread availability of AI-driven hacking tools on the Dark Web, while RAND's assessment of autonomy, reasoning, and tool-integration suggests that emerging AI systems may soon assume more complex operational functions within anonymized environments (Hodgson, Horton, & Malone, 2025).

From an offensive cyber-warfare perspective, the Dark Web operates as a distributed marketplace for AI-enabled cyber weapons and services, accelerating capability diffusion through models such as Malware-as-a-Service (MaaS), Phishing-as-a-Service (PhaaS), and Disinformation-as-a-Service (DaaS) (Ciancaglini et al., 2025). Reinforcement learning algorithms optimize attack strategies including lateral movement, privilege escalation, and IDS/SIEM evasion, while generative AI produces polymorphic malware, adversarial phishing content, and synthetic media for hybrid information operations. Defensive and intelligence organizations counter with AI-based monitoring frameworks that combine graph analytics, anomaly detection, and behavioural fingerprinting to infer adversarial networks, trace illicit financial flows, and anticipate cyber terrorist activity despite encrypted and pseudonymous conditions. This dual-use dynamic reinforces Gabrian's (2024) warning that AI-enabled cyber capabilities materially elevate national-security risk and highlights the need for governance mechanisms capable of addressing AI-driven escalation(Kela, 2025).

The convergence of AI and the Dark Web also accelerates the commodification of cyber capabilities. AI-powered tools for malware automation, phishing, and disinformation are increasingly traded in Dark Web markets, lowering the technical threshold for sophisticated attacks. Defensive actors employ AI-enabled analytics to detect weak signals of emerging threats and attribute malicious activity through behavioral and network-based inference rather than identity-centric methods. This adversarial co-evolution positions the Dark Web as a contested battlespace where AI simultaneously enables asymmetric warfare and supports counter-terrorism and cyber-intelligence operations. The absence of unified international legal frameworks governing AI-enabled cyber conflict further amplifies these challenges.

AI-enabled exploitation of Dark Web infrastructures aligns with NATO cyberspace-operations doctrine, functioning as an enabler of Cyberspace Intelligence, Surveillance, and Reconnaissance (C-ISR) and effects generation within joint operations. NATO's AJP-3.20 maps naturally onto AI-supported pipelines for indexing hidden services, inferring entities under pseudonymity, and conducting operational preparation of the environment (NATO, 2020). Graph learning, representation learning, transformer-based NLP, and anomaly detection accelerate indicator-to-warning conversion by extracting operational signals such as capability acquisition, malware diffusion, and recruitment surges from adversary-controlled ecosystems. In contexts

where the Dark Web facilitates terrorist coordination, propaganda, and fundraising, AI-driven automation enables monitoring and triage at scale, shifting analysis from identity-based attribution toward behavioural and infrastructural attribution.

From a U.S. DoD perspective, AI + Dark Web integration aligns with joint cyberspace-operations doctrine and the 2023 DoD Cyber Strategy's emphasis on defending forward and persistent engagement (DoD, 2023). Technically, this manifests as AI-accelerated kill-chain compression: automated reconnaissance, ML-assisted vulnerability discovery, and adaptive C2 and payload delivery leveraging Dark Web anonymity for staging and logistics. Defensive applications mirror this with AI-enabled hunt-forward analytics—graph embeddings to infer operational cells, clustering to detect emergent TTPs, NLP to identify operational intent, and blockchain analytics to map illicit finance pathways. These outputs feed joint targeting and campaign assessment, enabling disruption to be measured not only by takedowns but by changes in adversary access, resiliency, and TTP substitution under persistent engagement.

5. Operational Telemetry and Risk Quantification

Quantifying risk and assessing operational telemetry is key to understanding the nexus between the Dark Web, AI, and cyber warfare.

5.1 Macro-level Loss and Breach Telemetry

Operational risk modeling for Dark Web–mediated, AI-enabled intrusion must be anchored in empirical telemetry. At the macro level, incident-reporting data provides coarse but decision-useful bounds for expected loss. The FBI's Internet Crime Complaint Center (IC3) reported aggregate victim losses exceeding US$16 billion in 2024, a 33% increase relative to 2023, and indicates that cyber-enabled fraud accounts for the dominant share of losses. These macro-signals are not directly attributable to Dark Web activity; however, they contextualize the economic scale available to access brokers, malware operators, and monetization crews operating within anonymized ecosystems (FBI, 2025).

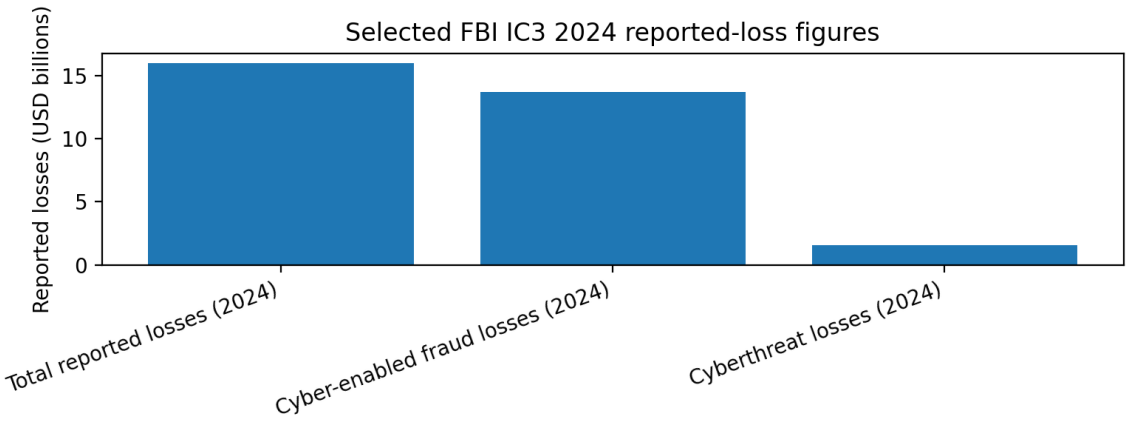

Figure 1: Selected FBI IC3 2024 reported-loss figures (values in USD billions) (FBI, 2025).

5.2 Capability Taxonomy Observed in Dark Web Markets

Dark Web markets commoditize discrete capability primitives that can be composed into full-spectrum campaigns. Table 1 provides an engineering taxonomy that maps common marketplace offerings to kill-chain phases and to representative defensive control families (e.g., identity hardening, vulnerability management, egress filtering).

Table 1: Engineering taxonomy of Dark Web capability primitives

Capability class	Typical market artefact/service	Kill-chain impact	Defensive control mapping
Initial access brokerage	Compromised VPN/RDP accounts; stealer logs; session cookies	Recon → Initial access	MFA, conditional access, credential hygiene, UEBA
Exploit enablement	N-day exploit chains; PoCs; exploit kits	Exploit	Patch SLAs, virtual patching, WAF/IPS signatures

Capability class	Typical market artefact/service	Kill-chain impact	Defensive control mapping
Payload delivery	Malware loaders; droppers; macro builders; email templates	Delivery/Install	Secure email gateway, sandboxing, attachment detonation
C2 resilience	Onion service C2; bulletproof hosting; fast-flux DNS	C2	Egress allowlists, TLS/JA3 fingerprinting, sinkholing
Monetization	Ransomware affiliates; crypto laundering; mule recruitment	Actions on objectives	Immutable backups, fraud analytics, blockchain tracing

5.3 Indicative Kill-chain Compression Under AI Augmentation

AI-assisted automation disproportionately accelerates early kill-chain phases by reducing human-in-the-loop latency for reconnaissance, target selection, content generation, and exploit parameterization. Figure 2 presents an illustrative (non-empirical) compression model intended to communicate the directionality of the effect: procurement and automation decrease cycle time per stage, increasing the number of parallelized intrusion attempts an actor can execute under a fixed resource budget (Hodgson, Horton, & Malone, 2025).

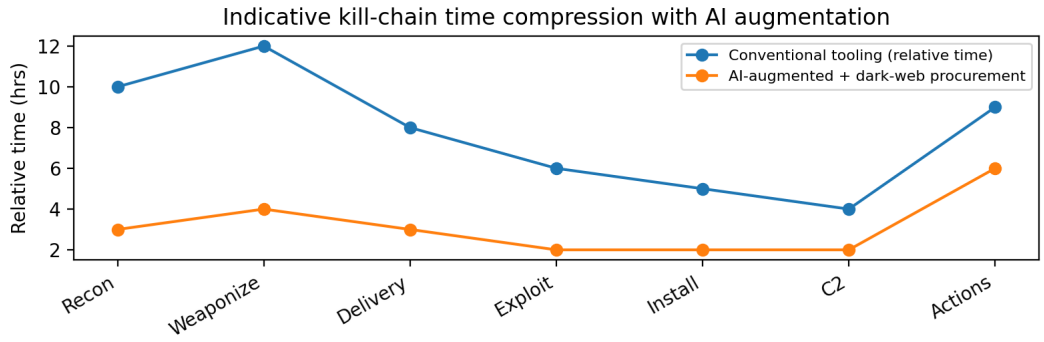

Figure 2: Indicative kill-chain time compression with AI augmentation (conceptual model) (Hodgson, Horton, & Malone, 2025)

5.4 Breach Telemetry Relevant to Initial-access Vectors

Independent breach investigations provide higher-fidelity indicators about prevailing initial-access vectors. Verizon's 2025 DBIR reports a 34% year-over-year increase in attackers exploiting vulnerabilities for initial access, finds that only 54% of perimeter-device vulnerabilities were fully remediated over the past year, and notes that ransomware was present in 44% of analyzed breaches (Verizon, 2025). These findings are operationally aligned with Dark Web market dynamics: access brokers monetize unpatched edge devices and compromised identities, while ransomware ecosystems externalize capability development through affiliate models.

Table 2: Selected cyber-risk telemetry informing Dark Web threat models

Telemetry indicator	Reported value	Engineering implication
Reported victim losses (IC3, 2024)	US$16B+	Macro-scale economic incentive for illicit capability markets
Cyber-enabled fraud losses (IC3, 2024)	US$13.7B	Monetization pressure favors credential theft and social engineering
Cyberthreat losses (IC3, 2024)	US$1.571B	Ransomware/data-breach ecosystems continue to scale
Perimeter vulns fully remediated (DBIR 2025)	54%	Patch latency creates durable exploit windows for access brokers
Ransomware presence in breaches (DBIR 2025)	44%	Affiliates profit from commoditized access and tooling
YoY increase in vulnerability exploitation (DBIR 2025)	34% increase	Prioritize attack-surface reduction for edge assets

6. Conclusions

The Dark Web has evolved from a privacy-enhancing communication layer into a strategic substrate for contemporary cyber warfare, mirroring the argument established in the introduction. Its anonymity architecture, marketplace economies, hidden-service infrastructures, and cryptocurrency systems collectively enable the procurement, coordination, and sustainment of offensive and defensive cyber operations. The integration of Artificial Intelligence amplifies these dynamics by accelerating reconnaissance, automating vulnerability discovery, and enabling adaptive adversarial behaviors that compress the cyber kill chain. As Gabrian (2024) observes, AI-driven hacking tools and automated malware kits are increasingly accessible within Dark Web ecosystems, while RAND's assessment of autonomy, reasoning, and tool-integration suggests that emerging AI systems may soon assume more complex operational functions within anonymized environments (Hodgson, Horton, & Malone, 2025). Together, these developments reinforce the introduction's central claim: the Dark Web is no longer a peripheral criminal enclave but a core operational environment within modern cyber conflict.

Within NATO and U.S. doctrinal frameworks, the Dark Web must therefore be conceptualized as a contested battlespace embedded within persistent cyberspace competition. Its infrastructures enable hybrid operations that blend espionage, information warfare, and cyber-enabled coercion under conditions of reduced attribution precisely the convergence highlighted in the introduction. As AI-enabled automation continues to reshape offensive and defensive tradecraft, doctrinal approaches must integrate intelligence fusion, rapid decision advantage, and persistent engagement to counter adversaries who leverage anonymity-preserving ecosystems for strategic effect. Future research must address the governance of AI-enabled cyber capabilities, the development of attribution methodologies capable of operating under pseudonymity, and the establishment of international norms regulating cyber-enabled hybrid warfare conducted through anonymity-preserving infrastructures. Advancing these areas is essential to ensure that emerging AI-driven capabilities do not outpace the legal, ethical, and strategic frameworks required to manage them.

Cybersecurity for Military Satellite Systems: Threats, Domains, and Engineering Countermeasures

Chuck Easttom
Vanderbilt, Georgetown, and Capitol Technology University, USA

chuckeasttom@gmail.com

Abstract: Military operations increasingly depend on satellite-enabled services for beyond-line-of-sight command-and-control, intelligence, surveillance and reconnaissance (ISR), missile warning, and precision navigation and timing. As space becomes more contested, adversaries can achieve operationally significant effects by cyber-compromising the end-to-end satellite enterprise rather than physically destroying spacecraft. A prominent example is the 24 February 2022 KA-SAT incident, where an intrusion into terrestrial management infrastructure and downstream user terminals disrupted connectivity for tens of thousands of users across Ukraine and Europe (CyberPeace Institute, 2022; Viasat, 2022). This paper develops an engineering-oriented threat model for military satellite systems across the ground, link, space, and user segments, then translates that model into implementable security controls and mission assurance design patterns. Using a quantitative, model-based risk assessment (Monte Carlo simulation) and control-to-attack-surface mapping, the paper prioritizes high-leverage mitigations such as privileged access management for mission operations, authenticated command and telemetry protection using standards-based space data-link cryptography, and zero trust architectures adapted to intermittent, high-latency RF environments (CISA, 2024a; CCSDS, 2020). Finally, the paper synthesizes resilience engineering principles—redundancy, graceful degradation, rapid reconstitution, and cyber-informed autonomy—into a pragmatic roadmap that aligns security investments with operational tempo. The central finding is that satellite cybersecurity must be treated as mission assurance: an integrated set of architectural, procedural, and cryptographic controls that preserve capability under sustained cyber pressure and enable recovery within tactically relevant timelines.

Keywords: Satellite cybersecurity, SATCOM, TT&C, Zero trust, Mission assurance, Space systems security

1. Introduction

Satellites underpin modern military power by enabling globally distributed forces to communicate, sense, navigate, and coordinate at speed and scale. NATO recognizes space as an operational domain and highlights that space capabilities are critical enablers for communications, navigation, early warning, and ISR in support of collective defense and crisis response (NATO, 2025). As constellations proliferate, the cyber-physical attack surface expands: spacecraft are controlled by ground mission operations centers (MOCs), telemetry-tracking-and-command (TT&C) infrastructure, key management systems, and a large population of geographically dispersed user terminals. These dependencies create numerous digital pathways for adversaries to generate denial, deception, or espionage effects without resorting to kinetic anti-satellite operations.

The KA-SAT incident illustrates the operational asymmetry of cyber-attacks against space services. Public reporting indicates that malware delivered via terrestrial management systems caused widespread modem disruption, producing cascading impacts beyond the immediate conflict area (CyberPeace Institute, 2022; SentinelOne, 2022). The implication for military systems is that mission assurance requires an enterprise view: protection of spacecraft alone is insufficient if ground or user segments can be compromised to deny or manipulate the mission.

This paper contributes an engineering-focused synthesis that (i) formalizes a threat model across satellite segments, (ii) presents a model-based quantitative risk ranking to guide prioritization, (iii) maps controls and standards—including CISA space-sector guidance and CCSDS data-link security—onto concrete attack surfaces, and (iv) operationalizes resilience patterns into an implementation roadmap (CISA, 2024b; RAND, 2024).

2. Satellite Enterprise Architecture and Cyber-Relevant Dependencies

Military space systems are end-to-end enterprises rather than monolithic spacecraft. From a security engineering perspective, the primary decomposition is into space, ground, link, and user segments, augmented by supply chain and lifecycle processes (Willbold et al., 2023). Each segment introduces distinct trust boundaries, timing constraints, and failure modes that must be incorporated into the security architecture.

2.1 Segment Decomposition

The space domain can be decomposed into multiple architectural segments in order to support systematic security engineering and risk analysis (Falco et al, 2024). Segmenting the satellite enterprise enables security controls to be mapped to specific operational domains, trust boundaries, and communication pathways within

the overall mission architecture. Such decomposition also allows threat modeling, attack-surface enumeration, and defensive control implementation to be applied in a structured and domain-specific manner across the satellite ecosystem.

- Space segment: satellite bus and payload, onboard avionics, flight software, software-defined radios (SDRs), inter-satellite links, attitude and orbit control, and onboard data handling.
- Ground segment: MOCs, TT&C stations, scheduling systems, key management infrastructure (KMI), mission data processing pipelines, and the supporting enterprise IT environment.
- Link segment: RF uplinks/downlinks for telemetry and command, mission payload data links, gateway backhaul, and cross-support interfaces.
- User segment: tactical SATCOM terminals, ship/aircraft modem stacks, handheld receivers, gateways, and coalition partner interconnects.
- Supply chain and lifecycle: multi-tier vendors, firmware provenance, software bill of materials (SBOM), cryptographic key lifecycle, and long-term sustainment over decade-scale lifetimes.

An infographic describing the segments is shown in figure 1.

Figure 1: Satellite Domain Segmentation

The attack surface grows with the number of operational satellites and associated terminals. The Union of Concerned Scientists database lists more than 7,560 operational satellites in orbit, illustrating the scale and

heterogeneity of the modern space environment (Union of Concerned Scientists, 2025). Greater scale increases the importance of automation, standardization, and robust identity-centric controls because manual, perimeter-driven approaches do not compose across distributed enterprises.

3. Threat Landscape and Attack Surfaces

The threat landscape must be systematically analyzed to identify potential attack surfaces across the satellite enterprise. Attack surface analysis involves identifying all interfaces, communication channels, software systems, and operational processes that could potentially be exploited by an adversary. Understanding these exposure points is a foundational step in cybersecurity engineering because it enables defenders to prioritize mitigation strategies, develop layered defensive architectures, and reduce the probability of successful exploitation across the ground, link, space, and user segments.

3.1 Ground-segment Intrusion and Mission Operations Compromise

Ground networks frequently contain conventional IT services such as identity providers, remote administration tooling, virtualized computers, and vendor maintenance channels. Adversaries can exploit misconfigurations, unpatched vulnerabilities, or compromised credentials to traverse from enterprise networks into mission operations enclaves. Once inside, attackers can disrupt scheduling, corrupt mission data pipelines, or tamper with command authorization workflows, achieving disproportionate operational impact without interacting directly with spacecraft.

3.2 TT&C Compromise and Command Authority

TT&C links represent the highest-consequence control surface because they encode command authority. Attack vectors include unauthorized command injection, replay of previously valid commands, manipulation of time-tagged command sequences, and corruption of telemetry to induce operator misinterpretation. Inconsistent cryptographic protection and operationally fragile key management remain recurring weaknesses; consequently, standards-based link-layer security and robust key lifecycle management are foundational countermeasures (CCSDS, 2020; CCSDS, 2020a).

3.3 User-terminal and Tactical Edge Exploitation

Tactical terminals operate in contested environments with constrained physical security and complex logistics. Because terminals are numerous, sometimes commercially derived, and frequently forward-deployed, they are attractive scaling targets. Terminal compromise can expose cryptographic material, enable traffic manipulation, or provide a pivot into gateway infrastructure. The KA-SAT event demonstrated a terminal-focused disruption mode at scale (CyberPeace Institute, 2022).

3.4 Supply Chain and Long Lifecycle Vulnerabilities

Spacecraft lifecycles span a decade or longer, while many embedded components have shorter support windows. Patch logistics are constrained by uplink bandwidth, certification processes, operational risk, and limited contact windows. These constraints elevate the importance of secure-by-construction engineering, reproducible builds, SBOM-driven vulnerability management, and cryptographic verification of updates. Space-specific risk management guidance emphasizes that cybersecurity requirements must be planned early and integrated with system engineering rather than retrofitted after launch (CISA, 2024b).

3.5 Historical Incidents and Observed Patterns

Public reporting indicates that satellite systems have been subject to cyber interference via ground infrastructure. For example, reports describe interference affecting NASA's Terra and the Landsat-7 system in 2007–2008, accessed via a ground station, underscoring the criticality of ground-segment security (Space.com, 2011; Satellite Today, 2011). In 2014, media reporting described a cyber intrusion affecting the U.S. National Oceanic and Atmospheric Administration network supporting weather operations, highlighting that space-enabled services are exposed through terrestrial IT dependencies (CBS News, 2014). These cases reinforce a consistent pattern: ground and user segments are often the most accessible adversary entry points, while the operational impact can manifest in the space mission.

4. 4. Quantitative, Model-based Risk Assessment

Because incident data for national security space systems is sparse and frequently classified, programmatic prioritization commonly relies on model-based risk assessment. This section presents a lightweight quantitative

approach intended to support engineering decision-making. The analysis uses Monte Carlo simulation to propagate uncertainty in likelihood and impact for representative threat vectors and to produce relative risk rankings. Results are illustrative rather than empirical; they should be calibrated with program-specific telemetry, vulnerability data, and red-team results.

4.1 Methodological Framework

The proposed approach employs a stochastic risk propagation model using Monte Carlo simulation to estimate the distribution of mission risk across heterogeneous threat vectors. Each threat vector is parameterized by likelihood of successful exploitation modeled as a Beta distribution, and operational impact severity modeled as a lognormal distribution. The resulting risk functional is defined as the product of likelihood and impact.

Monte Carlo sampling (N = 20,000) is used to estimate expected risk, tail risk (95th percentile), and higher-order statistical properties. This formulation aligns with probabilistic risk assessment methodologies used in safety-critical aerospace systems and extends them to cyber-physical threat domains in the space sector (Varadharajan & Suri, 2024; Falco et al., 2024; Khan et al., 2024).

Uncertainty is treated explicitly through wide prior distributions and scenario-based stress testing. Epistemic uncertainty is captured through expert-informed priors, while aleatory uncertainty reflects inherent stochastic variability in system behavior.

4.2 Results

The simulation outputs should be interpreted as relative prioritization indicators rather than absolute measures. Ground-segment intrusion demonstrates the highest expected risk due to accessibility and control-plane centrality. Conversely, TT&C compromise and supply-chain insertion exhibit lower likelihood but significantly higher tail risk, indicating catastrophic mission consequences.

Table 1: Illustrative risk model outputs (relative units; Monte Carlo simulation)

Threat vector	Segment	Likelihood (mean)	Impact (median)	Risk (mean)	Risk (P95)
Ground-segment intrusion	Ground	0.286	19.9	6.86	17.58
TT&C command compromise	Link/Space	0.074	36.8	3.14	8.81
User-terminal compromise	User	0.200	18.0	4.31	11.26
Supply-chain insertion	Supply chain	0.057	44.7	3.23	10.03
Data/telemetry integrity attack	Link/Space	0.123	24.4	3.50	9.55

Figure 2 visualizes the relative risk ranking from the model; programs should use the ranking to focus assurance effort on the highest-consequence, highest-accessibility pathways first.

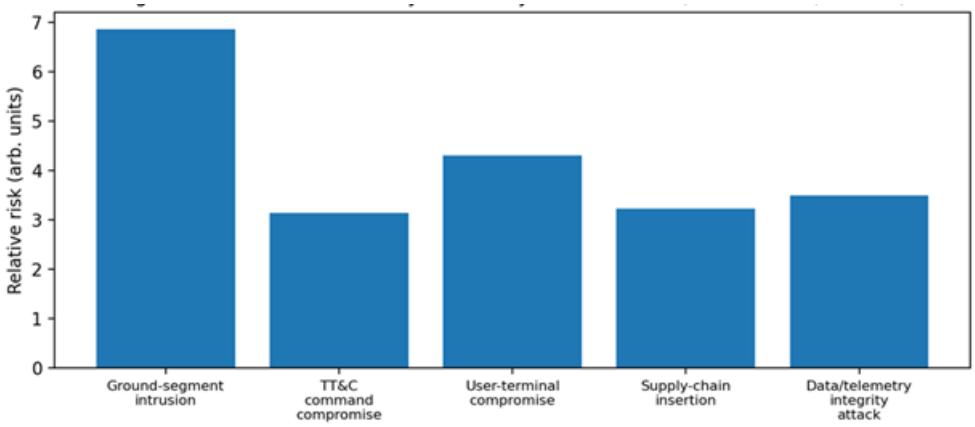

Figure 2: Modeled relative cyber-risk by threat vector (illustrative; Monte Carlo, N=20,000)

User-terminal compromise demonstrates systemic scaling effects, where moderate likelihood combined with large fleet size produces substantial aggregate risk. These findings are consistent with observed attack patterns and recent scholarship on space cyber resilience and attack-surface growth in satellite ecosystems (Varadharajan & Suri, 2024; Khan et al., 2024; Falco et al., 2024).

5. Security Engineering Controls and Architectures

Once the attack surface has been identified and characterized, the next phase of the security engineering process involves evaluating the security controls and architectural safeguards that protect each system component. This assessment includes analyzing authentication mechanisms, cryptographic protections, network segmentation strategies, and operational security procedures to determine their effectiveness against identified threat vectors. Through this process, organizations can systematically identify capability gaps, architectural weaknesses, and control deficiencies that must be addressed to achieve acceptable mission assurance levels.

5.1 Control Baselines and Governance

Military satellite cybersecurity programs typically adopt formal control baselines and assurance processes. CISA's space-sector guidance recommends using the NIST Cybersecurity Framework to develop profiles and risk mitigation plans and identifies common sources of cyber risk across space infrastructure (CISA, 2024b). For national security systems, additional overlays and profiles can improve fidelity by tailoring control intent to space-segment constraints. The Aerospace Corporation's space-segment cybersecurity profile provides a threat-focused rationale for tailoring controls to spacecraft avionics and mission contexts (The Aerospace Corporation, 2023).

5.2 Data-link Cryptography and Key Management

Cryptographic protection of telemetry and command is a prerequisite for preventing command injection and for preserving integrity under RF interception. The CCSDS Space Data Link Security (SDLS) family specifies services for authentication, confidentiality, and security parameter management at the data-link layer (CCSDS, 2020a). Engineering implementation requires: (i) hardware-backed key storage where feasible, (ii) rotation and revocation procedures compatible with limited contact windows, (iii) separation of mission keys from operator credentials, and (iv) resilient key distribution mechanisms that maintain continuity under degraded connectivity.

5.3 Zero Trust for Satellite Enterprises

Zero trust replaces implicit trust with explicit, continuously evaluated trust decisions based on identity, device posture, and policy. CISA's analysis of zero trust in the space environment identifies opportunities to apply zero trust tenets across ground, link, space, and user segments, while accounting for intermittent connectivity and latency (CISA, 2024a). Practically, this implies: strong identity for operators and devices, micro-segmentation of mission operations networks, policy enforcement points at control-plane interfaces, and continuous verification for privileged actions such as commanding and key management. Figure 3 describes zero trust control plane for satellites.

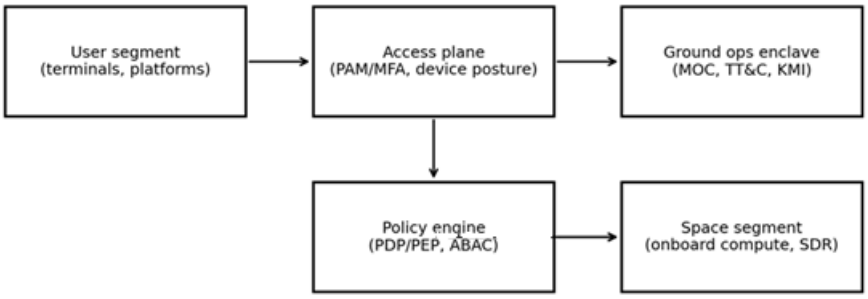

Figure 3: Reference zero trust control-plane adapted for satellite enterprises (conceptual)

5.4 Control-to-attack-surface Mapping

Table 2: Representative controls mapped to satellite attack surfaces

Control / mechanism	Primary segment	Engineering rationale
Privileged access management (PAM) + MFA for MOC/TT&C	Ground	Reduces credential theft and unauthorized operator actions; constrains lateral movement.
Network segmentation + unidirectional gateways for command paths	Ground/Link	Limits traversal from enterprise IT into operational enclaves; supports deterministic command pipelines.
SDLS authentication + encryption with robust key lifecycle	Link/Space	Mitigates command injection/replay and RF interception; preserves telemetry integrity.
Secure boot + signed updates + SBOM-driven vulnerability mgmt	Space/User/Supply chain	Reduces firmware insertion risk; improves patch trustworthiness and auditability.
Anomaly detection on TT&C telemetry and command sequences	Ground/Link	Detects deception and abnormal state transitions; supports rapid containment.
Degraded-mode operations and reconstitution playbooks	All	Enables mission continuation and rapid recovery under cyber disruption (RAND, 2024).

6. Resilience Engineering and Mission Assurance

Resilience engineering, sometimes referred to as reliability engineering, focuses on designing systems that can maintain operational capability despite failures, attacks, or unexpected disruptions. In complex cyber-physical systems such as military satellite architectures, resilience is evaluated using quantitative engineering methodologies including reliability modeling, failure mode analysis, and probabilistic risk assessment. These techniques allow engineers to measure system robustness, identify single points of failure, and design architectures that maintain mission functionality even when components are degraded or compromised.6.1 Resilience as a design requirement.

Perfect prevention is infeasible in complex, long-lived satellite enterprises. Mission assurance therefore treats resilience—continued operation and rapid recovery under attack—as a first-class requirement. RAND defines space mission assurance as deterring adversaries, countering risk from man-made and natural threats, and pursuing resilient architectures that sustain mission outcomes even when components fail or are compromised (RAND, 2024).

6.1 Engineering Patterns for Resilience

- Functional redundancy: multi-path communications (SATCOM + terrestrial backhaul), redundant ground stations, and cross-band contingency links.
- Diversity: heterogeneity across vendors, waveforms, and software stacks to reduce common-mode failure and supply-chain monoculture.
- Graceful degradation: pre-planned reduced capability modes (e.g., lower data-rate, reduced ISR product fidelity) that maintain critical functions under constraint.
- Rapid reconstitution: scripted rebuilds of ground services, golden images for terminals, and contingency keying material to restore trust quickly after compromise.
- Cyber-informed autonomy: onboard fault isolation and safe-mode transitions triggered by detected command anomalies or inconsistent state estimation.

6.2 Operational Metrics

Resilience must be measurable. Programs should define target recovery time objectives (RTO) and recovery point objectives (RPO) for mission services, then align engineering investments accordingly. For example, an RTO measured in hours for SATCOM service restoration implies pre-positioned terminal rekey capability, automated configuration management, and rehearsed playbooks for switching to alternate gateways. Where feasible, programs should instrument security-relevant telemetry—authentication failures, anomalous command sequences, and configuration drift—to support rapid triage and forensics.

7. Recommendations and Implementation Roadmap

Based on the previously developed threat model, the current cybersecurity standards landscape, and the results of model-based risk prioritization, a phased implementation roadmap can be constructed for defense organizations seeking to modernize satellite cybersecurity. This roadmap emphasizes controls that provide the highest marginal improvement in mission assurance while minimizing operational disruption and integration complexity. The proposed sequence addresses both technical and organizational transformation requirements across near-term, mid-term, and long-term horizons.

7.1 Near-term (0–12 Months)

Near-term efforts focus on high-impact, low-disruption controls. Organizations should implement privileged access management with hardware-backed authentication and just-in-time privilege escalation. Mission networks should be segmented with clearly defined trust boundaries, including isolation of TT&C command pathways using unidirectional gateways where feasible. Incident response capabilities must be operationalized through playbooks addressing terminal compromise, rapid re-imaging, and cryptographic key revocation. Regular cyber exercises should be conducted to validate response effectiveness.

- Enforce strict privilege access management, and time-bound privileged sessions for all mission operations and key management roles; eliminate shared accounts.
- Establish a segmented mission operations with segment boundaries well defined and secured.
- Create and exercise incident response playbooks for modem/terminal fleet compromise, including rapid re-imaging and key revocation.

7.2 Mid-term (12–36 Months)

Mid-term efforts introduce architectural transformation. Zero trust principles should be applied across mission interfaces with continuous authorization based on identity, device posture, and context (CISA, 2024a; Falco et al., 2024; Khan et al., 2024).

Secure software engineering practices, including reproducible builds, SBOM integration, and signed firmware pipelines, should be adopted. Telemetry-driven anomaly detection should be deployed across TT&C and mission data pipelines and integrated into a centralized security operations capability.

Threat intelligence integration should incorporate space-specific adversary tactics, techniques, and procedures, leveraging structured adversary-behavior frameworks and recent empirical analyses of satellite cyber-attack paths to support detection engineering and campaign analysis (Willbold et al., 2023; Khan et al., 2024; Peled et al., 2025).

- Adopt zero trust policy enforcement at mission control interfaces, integrating device posture and continuous authorization for high-consequence actions (CISA, 2024a).
- Introduce rigorous software engineering requirements, reproducible builds, and signed update pipelines for both spacecraft and terminal firmware; integrate supply chain risk assessment into acquisition.
- Instrument TT&C and mission data pipelines with anomaly detection tuned to satellite operational state models; integrate with a security operations capability.
- Integrate space oriented cyber threat intelligence into the development pipeline.

7.3 Long-term (36+ Months)

Long-term efforts focus on autonomous and resilient architectures. Cyber-informed autonomy should be embedded in spacecraft to enable anomaly-triggered safe modes and onboard decision-making under contested conditions. Constellation-level resilience should be engineered through distributed mission execution, authenticated inter-satellite links, and dynamic re-tasking. Coalition interoperability should be enabled through federated identity and attribute-based access control frameworks. These capabilities align with emerging doctrines of space cyber resilience and contested space operations (Falco et al., 2024; Khan et al., 2024; RAND, 2024).

- Engineer cyber-informed autonomy and safe-mode logic to maintain spacecraft survivability and limit adversary command authority.

- Design constellation-level resilience: diverse ground access, inter-satellite crosslinks with authenticated routing, and re-tasking strategies to sustain mission coverage under partial compromise.
- Standardize coalition interoperability through shared cryptographic and identity frameworks while maintaining compartmentalization and least privilege.

8. Conclusion

Military dependence on satellites makes space systems high-value cyber targets. Recent incidents demonstrate that adversaries can generate strategic effects by compromising ground infrastructure and user terminals rather than engaging in kinetic anti-satellite actions (CyberPeace Institute, 2022). Effective satellite cybersecurity therefore requires an enterprise mission assurance posture: structured risk management, standards-based link security and key management, identity-centric architectures such as zero trust, and resilience patterns that enable continued operation and rapid recovery (CISA, 2024a; RAND, 2024).

This study provides an engineering-oriented framework for analyzing satellite cyber risk and translating that analysis into actionable defensive architectures. However, satellite cybersecurity remains an evolving field that requires continued interdisciplinary research combining space systems engineering, network security, and operational mission assurance. Future work should focus on improved telemetry-driven threat detection, formal verification of satellite command systems, and integration of cyber resilience mechanisms directly into spacecraft autonomy and constellation-level architectures.

Ethics declaration: This research did not involve human subjects and thus no ethical clearance was required.

AI declaration: AI was only used to assist in making Figure 1. I created an initial figure then requested that ChatGPT improve that figure.

Offensive Cyberspace Operations: Operational Logic, Strategic Utility, and Governance in Contemporary Cyber Conflict

Chuck Easttom
Vanderbilt, Georgetown, and Capitol Technology University, USA

chuckeasttom@gmail.com

Abstract: Offensive cyberspace operations (OCO) have matured into a routine instrument of state power across the spectrum from day-to-day strategic competition to armed conflict. Yet OCO remains unusually difficult to conceptualize and govern because cyberspace is privately owned, technically volatile, and operationally interdependent with civilian critical infrastructure and global software supply chains. This paper develops a doctrinally grounded, technically informed framework for analyzing OCO across tactical, operational, and strategic levels of war while avoiding tradecraft. It models OCO effectiveness as an access-to-effects pipeline constrained by target system dynamism, intelligence requirements, identity and access management (IAM) complexity, tool exposure risk, and the probability of uncontrolled propagation or collateral impact. Empirically, contemporary intrusion data underscores that exploit-driven initial access is common and that remediation timelines often lag adversary tempo, reinforcing the perishable nature of access (Verizon, 2025; Mandiant, 2025). Strategically, OCO can enable campaign disruption, deterrence by denial, and information advantage, but their coercive predictability is limited, and their escalation externalities can exceed those of conventional fires in tightly coupled socio-technical systems. The paper synthesizes public doctrine, national strategies, and contemporary legal debates, emphasizing that credible governance must integrate military, intelligence, diplomatic, and software-engineering risk perspectives, including vulnerability-equities decisions and supply-chain assurance. It further highlights accelerants—AI-enabled capability scaling and the commodification of access through criminal markets—that compress decision timelines and blur state–non-state boundaries. The conclusion proposes a research and policy agenda centered on measuring effects over time, institutionalizing robust review and oversight, and strengthening resilience to manage the distinctive systemic risks of offensive cyber power.

Keywords: Offensive cyber operations, Cyberspace operations, Persistent engagement, Defend forward, Escalation, International law, NATO, Governance, AI-cyber nexus, Underground markets, Cyber-physical risk, Vulnerability equities

1. Introduction

Cyberspace has become a persistent arena of geopolitical contestation in which states and non-state actors continuously probe, exploit, and manipulate information systems to obtain intelligence, impose costs, and shape decision environments. Unlike traditional domains, the cyber domain is constituted largely by privately operated infrastructure and software-defined architectures that change rapidly through patching, configuration drift, container redeployments, identity policy updates, and supply-chain releases. These structural properties create a strategic paradox: cyber operations can project power without physical border crossings, yet the same connectivity that enables action also amplifies systemic spillover risk and the probability of collateral impact on civilian services (Theohary, 2024).

Operationally, modern targets are hybrid by default: enterprise networks fuse on-premises assets with cloud control planes, software-as-a-service (SaaS) tenants, managed identity providers (IdPs), and third-party integrations. The attack surface therefore includes not only hosts and networks, but also API permissions, federated authentication flows, secrets sprawl in CI/CD systems, and shared dependencies such as managed service providers (MSPs). For OCO, this increases both the intelligence burden—accurate modelling of a target's socio-technical configuration—and the governance burden—risk analysis for second-order effects in ecosystems not owned by the target state.

Offensive cyberspace operations differ from kinetic strike operations in ways that matter for both military doctrine and public oversight. Access is perishable; effects can be reversible, non-linear, and difficult to attribute; and operational success often depends on detailed intelligence regarding target configurations, defensive telemetry, and operator-controlled deconfliction (Joint Chiefs of Staff, 2018; Borghard and Lonergan, 2019). These features complicate deterrence signaling, post-operation battle damage assessment, and proportionality analysis. They also produce a persistent asymmetry between the rate of technological change (often days) and the pace of institutional decision processes (often weeks to months).

2. Definitions and Scope

U.S. doctrine frames cyberspace as a global domain within the information environment composed of interdependent networks, information systems, and embedded processors and controllers (Joint Chiefs of Staff, 2018). 'Cyberspace operations' describe the employment of cyberspace capabilities to achieve objectives in or

through cyberspace, including effects that can manifest outside the domain via cyber-physical coupling. Within that doctrinal frame, OCO are operations intended to project power by applying force in or through cyberspace to deny, degrade, disrupt, destroy, or manipulate adversary systems, data, or decision processes (Theohary, 2024).

This paper distinguishes OCO from closely related activity that is often operationally intertwined. Cyber espionage (commonly framed as cyber collection or CNE) seeks information advantage; it may share access pathways and infrastructure with OCO but typically aims for persistence and stealth rather than overt effect. Defensive cyberspace operations (DCO) focus on detection, mitigation, and active defense, while Department of Defense Information Network (DODIN) operations sustain mission networks. In practice, campaigning concepts such as persistent engagement and defend forward intentionally blur these boundaries, emphasizing continuous contestation and pre-emptive disruption of adversary infrastructure (U.S. Department of Defense, 2018; U.S. Cyber Command, 2022; Healey, 2019).

Scope is bound to strategic and operational analysis and explicitly omits tradecraft. Accordingly, discussion focuses on enduring technical constraints, risk dynamics, and governance mechanisms rather than procedural methods for intrusion, exploitation, or tool construction. Where technical terminology is used (e.g., 'control plane', 'EDR telemetry', 'privilege boundary'), it is intended to describe the risk surface and decision variables relevant to policy and command.

3. Policy and Legislative Context

OCO sits at the intersection of military activity, intelligence collection, and domestic legal controls. In the United States, operations may be conducted under military authorities (often associated with Title 10), intelligence authorities (often associated with Title 50), or hybrid arrangements combining intelligence preparation with military execution (Theohary, 2024). This legal geography shapes oversight, reporting, permissible objectives, and the ability to integrate effects with other instruments of national power—especially in the 'below-armed-conflict' space of strategic competition.

Strategic guidance since 2018 has emphasized a proactive posture. The 2018 DoD Cyber Strategy articulated defend forward, while U.S. Cyber Command describes persistent engagement as continuous contestation of adversary campaigns rather than episodic crisis response (U.S. Department of Defense, 2018; U.S. Cyber Command, 2022). The 2023 DoD Cyber Strategy summary similarly frames cyberspace operations as integral to campaigning and integrated deterrence (U.S. Department of Defense, 2023).

Governance also includes decisions about vulnerability retention versus disclosure. The Vulnerabilities Equities Process (VEP) formalizes deliberation over whether to disclose vulnerabilities to improve ecosystem security or retain them temporarily for national security purposes (The White House, 2017; Director of National Intelligence, 2024). In an era of high-tempo patching and 'patch-gap' exploitation, vulnerability policy functions as an operational variable: retention may enable access, but it can also increase systemic risk if the same weaknesses are discovered by adversaries, leaked, or widely exploited.

Table 1: Conceptual distinctions relevant to OCO governance

Activity lens	Primary objective	Typical success metric	Governance emphasis
OCO (effects)	Deny/degrade/disrupt/destroy/manipulate	Operational effect + controllability	Legal review + collateral/spillover risk
Cyber espionage (collection)	Information advantage	Persistence + exfil integrity	Counterintelligence + source protection
DCO	Defend systems and missions	MTTD/MTTR reduction	Resilience + incident response authority
DODIN ops	Network readiness and availability	Service uptime + compliance	Configuration control + supply-chain assurance

4. Analytical Approach: An Access-to-Effects Model

A useful analytic model must connect capability generation, operational employment, and strategic meaning. This paper adopts an 'access-to-effects' abstraction in which OCO are pipelines that convert privileged access into operational effects. Under this model, access is a perishable asset subject to detection, patching, credential

rotation, and architectural change; effects are contingent outcomes mediated by socio-technical systems, including automated defenses and organizational resilience (Healey, 2019; Borghard and Lonergan, 2019).

The model highlights a practical reality: many OCO failure modes occur before any payload-like mechanism is relevant. Failures include mis-modelled identity topologies, unanticipated cloud policy constraints, EDR detections at the telemetry layer, or the loss of an access pathway due to routine maintenance. The access-to-effects approach therefore treats intelligence preparation of digital terrain as analogous to weaponeering: operators must characterize dependencies, identify 'choke points' in workflows, and estimate the reliability and reversibility of potential effects.

Formally, the expected utility of an OCO action can be expressed as an engineering-style risk trade: EU ≈ P(access) × P(effect|access) × Value(effect) − [Risk(exposure) + Risk(spillover) + Risk(escalation)] × Cost. This is not a predictive equation so much as a decision framework: it forces explicit assumptions about probability, value, and externalities that can be challenged in review and oversight.

5. Operational Logic and Technical Constraints

The decisive factor in many OCO is not 'payload sophistication' but the fidelity of target system understanding. Contemporary environments integrate cloud services, identity and access management layers, software-defined networking, endpoint telemetry, and third-party dependencies that can change faster than a cyber operation's planning cycle. Configuration drift, patching, certificate rotation, and CI/CD deployments can invalidate assumptions and collapse access windows. Consequently, OCO are increasingly shaped by operational tempo and logistics—maintaining access in a moving target—rather than a one-time technical breakthrough.

Incident telemetry supports this access-centric framing. The 2025 Verizon Data Breach Investigations Report (DBIR) analyzed 12,195 data breaches across 139 victim countries, and found that credential abuse (22%), exploitation of vulnerabilities (20%), and phishing (16%) were leading known initial access vectors in non-error, non-misuse breaches (Verizon, 2025). The same report notes that perimeter device vulnerabilities were fully remediated only about 54% of the time, with a median of 32 days to complete remediation—an interval that can be operationally significant when adversaries pursue rapid exploitation (Verizon, 2025).

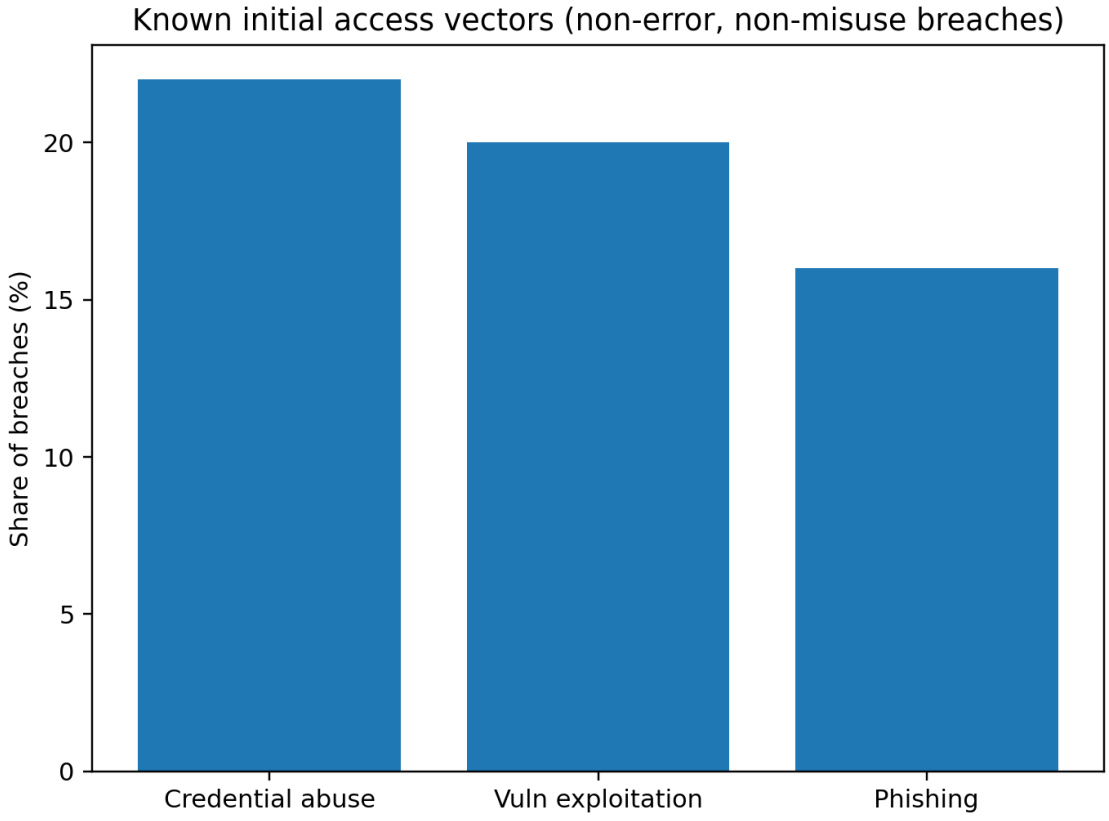

Figure 1: Known initial access vectors reported in Verizon DBIR 2025 (values shown are percentages). Source data: Verizon (2025)

From an operational perspective, the access-to-effects pipeline typically traverses multiple trust boundaries: external perimeter to identity plane, identity plane to workload plane, and workload plane to data plane. Each boundary introduces distinct defensive controls (e.g., MFA and conditional access at the identity layer, EDR and application allow-listing at endpoints, policy enforcement at cloud APIs). Maintaining operational security requires minimizing distinctive artifacts, managing observables, and deconflicting with other operations. Repeated use of a capability increases exposure risk, enabling defenders to detect, attribute, and mitigate, thereby reducing future utility (Borghard and Lonergan, 2019).

Reliability is also constrained by the heterogeneity of targets. Effects that depend on precise timing, specific library versions, or fragile assumptions about business logic can fail silently. Conversely, effects that propagate across shared dependencies—such as common management tooling, authentication services, or update channels—can exceed intended scope. For governance, this means technical review must include explicit 'blast radius' estimation and fail-safe considerations, not merely legal analysis.

Table 2: Access-to-effects pipeline and common constraint categories

Pipeline stage	Key artefacts	Constraint driver	Typical failure mode	Governance concern
Access establishment	Initial foothold, credentials/tokens	Patch gap; identity controls	Access burned by detection/rotation	Exposure risk; proportionality of entry
Privilege/positioning	Privileges, roles, trust relationships	IAM complexity; segmentation	Blocked by least privilege or policy	Deconfliction; scope creep
Persistence	Automation, renewal paths	Change management; monitoring	Breaks during updates/maintenance	Long-term systemic risk
Effect delivery	Triggers, dependencies, workflows	Target dynamism; safety constraints	Effect partial/reversible/unreliable	Controllability; civilian impact
Assessment & mitigation	Telemetry, restoration signals	Attribution ambiguity; IR maturity	Effects unmeasured or misattributed	Accountability; after-action learning

6. Interdependence and Collateral Effects

Cyberspace interdependence is a structural property of modern digital systems: societies share software stacks, hardware supply chains, managed service providers, and global routing and naming infrastructure. Offensive actions can therefore generate second- and third-order effects through shared dependencies, technical propagation, or operational disruption in adjacent ecosystems. The operational problem becomes one of controlling effects in a complex adaptive system rather than in a closed test environment.

Public attributions of the 2017 NotPetya incident highlight the systemic nature of spillover risk: a campaign aimed at Ukrainian targets rapidly caused widespread disruption and economic harm to global firms (UK Government, 2018; The White House, 2018; CISA, 2017). Such cases illustrate why proportionality and precautions, central concepts in international humanitarian law, must be operationalized as engineering and risk-analysis practices, not treated solely as legal abstractions (Davis et al., 2022; ICRC, 2019).

From a technical risk perspective, collateral pathways include: (1) shared authentication services (IdPs, federation), (2) shared management planes (remote monitoring and management tools, MSP platforms), (3) shared update mechanisms (software repositories and package registries), and (4) shared industrial and critical infrastructure dependencies (OT safety systems and supervisory control networks). Accordingly, resilience engineering—segmentation, redundancy, offline backups, immutable logging, and rapid restoration—functions as a strategic variable shaping both offensive feasibility and defensive survivability.

7. Strategic Purposes and Escalation Dynamics

OCO can support coercion (Fischerkeller, 2022), deterrence, campaign disruption, and information advantage, but these objectives are not equally predictable. Research on cyber escalation emphasizes that cyber operations frequently generate limited and uncertain costs, can be difficult to signal credibly, and often produce non-escalatory patterns of response (Borghard and Lonergan, 2019; Lin, 2012). These features reduce coercive leverage relative to conventional punishment strategies and complicate crisis bargaining.

Persistent engagement logic reframes strategic utility toward deterrence by denial and campaign disruption: continuous interference with adversary cyber capabilities, infrastructure, and enabling resources to impose friction and deny freedom of maneuver (Fischerkeller, 2022; Healey, 2019; U.S. Cyber Command, 2022). OCO can also support information advantage by degrading data integrity or situational awareness in ways that slow adversary decision cycles. Yet such effects may be perceived as escalatory if they threaten strategic stability or appear preparatory to kinetic action, underscoring the need for calibrated signaling and integrated crisis management.

A useful strategic lens is to treat OCO as 'campaign enablers' rather than stand-alone coercive instruments. In integrated operations, cyber effects may shape access to the electromagnetic spectrum, protect force flow, degrade adversary logistics, or contest command-and-control (C2) systems. However, because cyber effects can be transient and rapidly mitigated, campaign planners must consider persistence of effect over time, defender adaptation, and the opportunity cost of capability exposure.

8. International Law and Norms

UN processes have repeatedly affirmed that international law, including the UN Charter, applies to state behavior in cyberspace (UN General Assembly, 2015; 2021; 2023). Operational challenges arise from threshold classification: determining when cyber operations constitute a use of force, when they qualify as an armed attack triggering self-defense, and how to assess scale and effects when harm is economic, informational, or distributed.

States increasingly publish national positions. France emphasizes sovereignty and due diligence as well as the availability of responses under international law (France, 2021). The United States similarly emphasizes that existing international law governs cyber operations and has articulated a 'victim's perspective' focused on harms imposed (Davis et al., 2022; Visek, 2024). Debates persist over the legal content of sovereignty in cyberspace and the precise contours of countermeasures.

During armed conflict, international humanitarian law (IHL) limits cyber operations used as means or methods of warfare. The ICRC stresses that IHL applies fully in cyberspace, including distinction, proportionality, and precautions, and warns that cyber operations can seriously affect civilian infrastructure with potential human harm (ICRC, 2019; ICRC, 2023). Voluntary norms and confidence-building measures endorsed in UN processes aim to reduce misperception and escalation risk, while scholarly restatements such as the Tallinn Manual provide non-binding legal clarification.

9. Alliances and Multinational Cyber Operations

Alliances shape both the feasibility and legitimacy of OCO. NATO has recognized cyberspace as a domain of operations and has affirmed that a cyberattack could, in certain circumstances, trigger Article 5 collective defense commitments on a case-by-case basis (NATO, 2014; NATO, 2023). Nonetheless, NATO emphasizes that offensive cyber capabilities remain primarily national, making coalition cyber effects dependent on sovereign contributions and political authorization.

Multinational coordination is constrained by divergent legal frameworks, political risk tolerances, classification regimes, and technical interoperability. Shared operational pictures may be limited by data-sovereignty concerns and by differing incident response standards. Effective burden sharing therefore includes information sharing, deconfliction mechanisms, and shared risk frameworks for collateral effects—not only investment in capabilities.

10. Governance, Oversight, and Institutional Design

OCO governance must balance operational secrecy, strategic effectiveness, and democratic accountability. Secrecy preserves access and sources, but it limits external scrutiny and can impede institutional learning. Speed increases operational relevance, but it can erode legal review and systemic risk analysis. Accountability requires oversight by elected officials and watchdog institutions, yet the technical and classified nature of OCO creates persistent information asymmetries (Theohary, 2024; U.S. Government Accountability Office, 2025).

Governance frameworks benefit from translating legal and strategic requirements into engineering-style controls: defined risk thresholds, explicit collateral analyses, red-team validation of containment assumptions, and post-operation mitigation plans. A practical approach is multidisciplinary review that combines legal analysis with software-engineering risk assessment (e.g., dependency mapping, 'blast radius' modelling, rollback planning, and verification of restoration).

Broader cyber risk data provides context for why governance must treat spillover seriously. IBM's 2025 Cost of a Data Breach report shows the global average breach cost at USD 4.44 million in 2025, following USD 4.88 million in 2024, and provides a multi-year trend useful for strategic risk framing (IBM, 2025). While the report is not specific to state OCO, it illustrates the magnitude of economic externalities that can arise from cyber incidents and therefore the importance of precautionary controls for operations that could affect civilian systems.

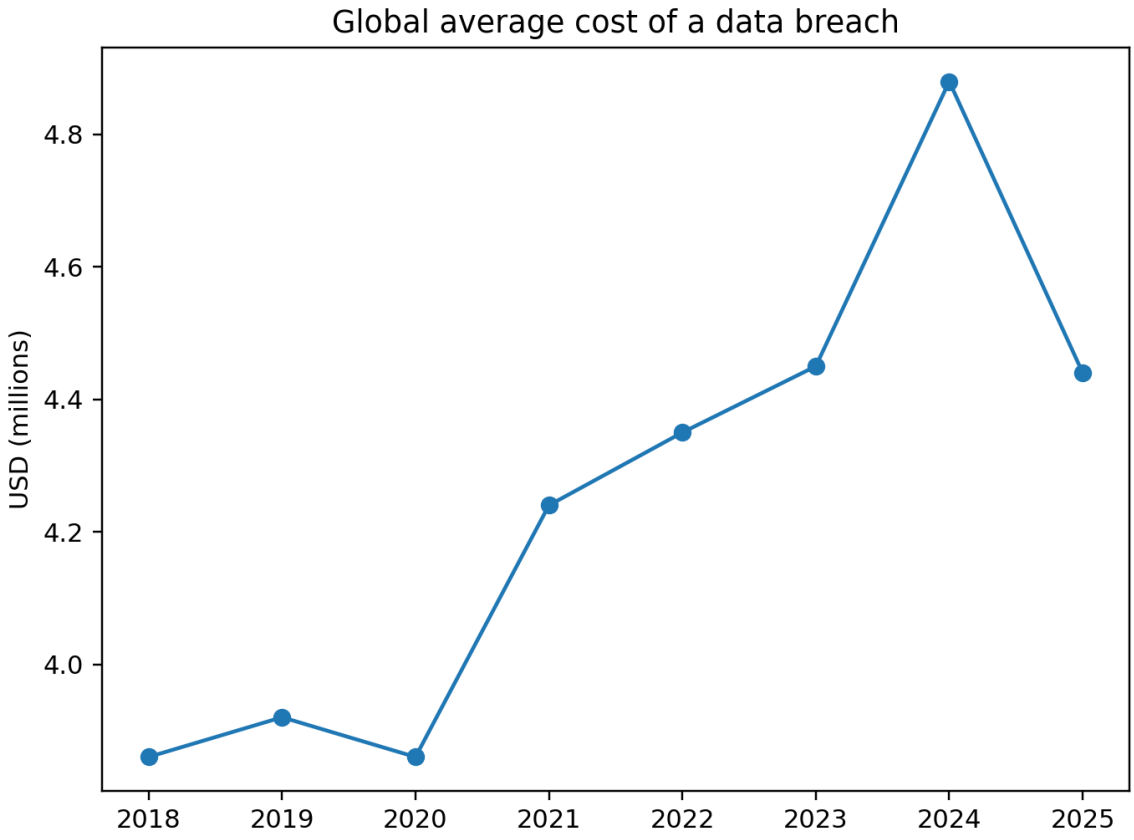

Figure 2: Global average cost of a data breach (USD millions), 2018–2025. Source data: IBM (2025)

11. Measuring Effects: Metrics and Assessment

Measuring OCO effectiveness is difficult because cyber effects are often indirect, mediated by defender adaptation, and confounded by concurrent instruments of power (sanctions, diplomacy, information operations). Unlike kinetic strikes, where crater analysis and sensor logs can approximate immediate physical damage, cyber 'battle damage assessment' may hinge on telemetry access, organizational reporting, and probabilistic inference.

Operational assessment therefore benefits from layered metrics: (1) access metrics (persistence duration, privilege depth, lateral reach), (2) effect metrics (service degradation, data integrity impacts, decision-cycle delays), and (3) externality metrics (spillover indicators, third-party impacts, and exposure costs). For governance, these metrics support after-action learning and provide a defensible basis for proportionality and precaution documentation.

Incident response datasets provide a proxy for the attacker–defender tempo relevant to access perishability. Mandiant reports that exploits were the initial infection vector in 33% of its 2024 investigations, and that global median dwell time rose to 11 days from 10 days in 2023 (still below 16 days in 2022) (Mandiant, 2025). Shorter dwell times can reduce the feasibility of long-horizon access operations, shifting emphasis toward rapid exploitation, automation, and operational security.

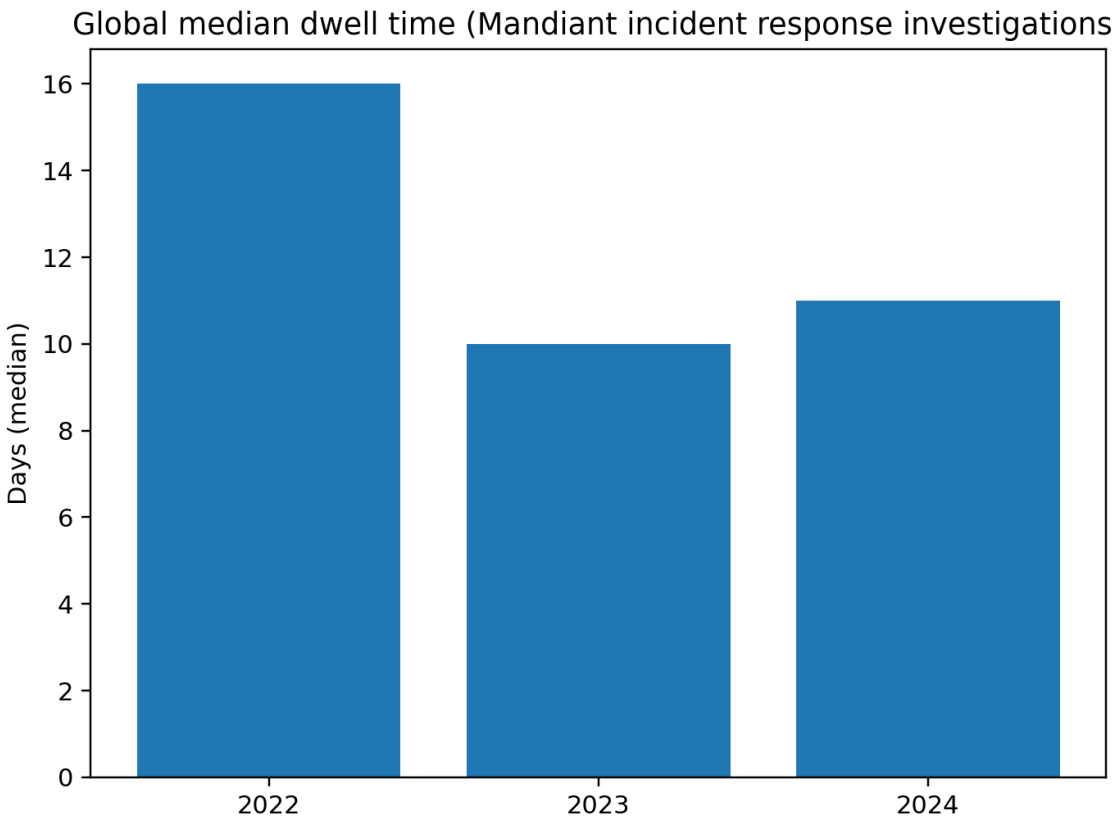

Figure 3: Global median dwell time (days). Source data: Mandiant (2025)

12. Emerging Accelerants: AI-Cyber Nexus and Access Commodification

Two accelerants intensify OCO's operational and governance challenges. First, AI-enabled systems can reduce the marginal cost of reconnaissance, language-specific social engineering, code analysis, and anomaly detection—compressing decision cycles and enabling higher-tempo campaigns. Second, underground markets increasingly commodify access and data through 'initial access brokers' and credential marketplaces, creating a shadow logistics layer for intrusion activity (Europol, 2025).

Recent breach research also points to AI as both an attack multiplier and a governance challenge. IBM reports that 16% of breaches involved attackers using AI, and that 13% of organizations reported breaches involving their AI models or applications; among those organizations, 97% lacked proper AI access controls (IBM, 2025). This suggests that AI systems are emerging as high-value targets and that weak governance—shadow AI, unmanaged plugins, and unreviewed API integrations—can create new pathways for compromise.

At the enterprise boundary, Verizon reports that 15% of employees routinely accessed generative AI platforms on corporate devices, increasing the potential risk for data leakage (Verizon, 2025). For state operators, these trends blur the line between traditional cyber operations and information operations, as AI-mediated influence, credential theft, and data poisoning can intersect with offensive access campaigns.

For governance, the AI-cyber nexus implies that review processes must incorporate model supply-chain risk (plugins, APIs, agents), data residency and privacy constraints, and the possibility of unintended propagation through automated systems. The same logic supports integrating secure-by-design practices, strong identity controls, and continuous monitoring into national cyber posture—reducing incentives to retain vulnerabilities for offensive gain while raising the cost of adversary exploitation.

13. Research and Policy Agenda

Four priorities stand out. First, the field needs rigorous methods to measure OCO effectiveness over time, distinguishing transient disruption from durable degradation and accounting for defender adaptation, restoration timelines, and capability exposure costs. Second, escalation modeling must integrate technical

ambiguity, interdependence spillover, and political crisis dynamics, especially as cyber operations intersect with critical infrastructure and military command systems (Borghard and Lonergan, 2019; Lin, 2012).

Third, policy and research should focus on the AI-cyber nexus and access commodification. AI may accelerate capability generation while introducing new vulnerabilities through autonomous agents and model supply chains; underground markets for initial access and data create a proxy enablement layer that can complicate deterrence and attribution (Europol, 2025; IBM, 2025). Fourth, governance mechanisms should mature toward multidisciplinary review practices that combine legal analysis with software-engineering risk assessment, enabling systematic consideration of collateral effects, long-term systemic vulnerability, and accountable decision records suitable for after-action learning under appropriate oversight.

14. Conclusion

OCO are an enduring element of contemporary state competition and military power, but they are constrained by perishable access, uncertain and interdependent effects, and governance challenges intensified by secrecy and rapid technological change. An access-to-effects model clarifies why OCO require intelligence, engineering rigor, and exposure management as much as technical ingenuity. Strategically, OCO can disrupt adversary campaigns and support deterrence by denial and information advantage, yet escalation and legitimacy risks demand robust oversight and prudent integration with other instruments of national power. As AI-enabled capability scaling and underground commodification accelerate the offense–defense cycle, states and alliances will require disciplined frameworks for risk assessment, legal and normative clarity, and resilience engineering to manage the systemic externalities of offensive cyber power.

Information Campaigns in Irregular Warfare: A Framework for Expanding the Threshold of Competition

Nickolas Elekes, Timothy Shives and Michael Richardson
Naval Postgraduate School, Monterey, California, USA

Nickolas.elekes@nps.edu
Timothy.Shives@nps.edu
mrichard@nps.edu

Abstract: Contemporary irregular warfare increasingly unfolds through coordinated information campaigns designed to shape adversary perception, fragment decision-making, and expand competitive space below traditional escalation thresholds. While deterrence frameworks have historically emphasized military capability and economic leverage, modern competitors employ narrative operations, psychological pressure, and legitimacy contests to achieve strategic effects without decisive kinetic engagement. Classic coercion theory emphasizes that influence over adversary decision conditions often matters more than direct force application, particularly in ambiguous competitive environments (Schelling, 1966; Freedman, 2013). This paper proposes a decision-centric framework for information campaigns in irregular warfare that explains how coordinated narrative, psychological, and cyber-enabled information actions expand the threshold of competition. The framework integrates deterrence theory, irregular warfare doctrine, and gray zone competition research to show how information campaigns generate cumulative strategic effects through tempo disruption, legitimacy shaping, and perception control. Case evidence from Hizballah's psychological campaign, Chinese gray zone coercion, and contemporary Russian information operations illustrates how sustained campaigns produce denial, cost imposition, and delegitimization effects without triggering conventional escalation (Wehrey, 2002; Lin et al., 2022; Kalenský and Osadchuk, 2024). The contribution of this study is a structured campaign framework that links information actions to decision advantage and operational outcomes. This model supports parallel, multidomain action and helps practitioners design campaigns that shape competitive conditions before escalation thresholds are crossed.

Keywords*:* Information campaigns, Irregular warfare, Gray zone competition, Decision advantage, Psychological operations, Narrative strategy

1. Introduction

Irregular warfare has reemerged as a central feature of strategic competition, but its contemporary form differs from earlier insurgency-centric models. Modern competitors increasingly rely on coordinated information campaigns to influence perception, shape legitimacy, and alter adversary decision environments without crossing traditional escalation thresholds. These campaigns operate through narrative construction, psychological pressure, selective truth disclosure, and cognitive framing rather than decisive battlefield engagements. Competitive advantage is therefore often determined by decision influence and interpretive control rather than force superiority alone.

Classic coercion and deterrence theory emphasizes that shaping an adversary's expectations and perceived choices can be more decisive than the direct application of force (Schelling, 1966). Modern strategy scholarship similarly argues that competition frequently turns on perception, credibility, and narrative framing rather than material capability alone (Freedman, 2013). This insight is especially relevant in irregular warfare environments where legitimacy, narrative control, and psychological effects shape operational space. Clausewitz's conception of conflict as political and perceptual underscores that belief and legitimacy are operational variables, not merely contextual ones (Clausewitz, 2006).

Recent gray zone competition research shows that state and non-state actors deliberately design campaigns to achieve cumulative advantage through ambiguity, deniability, and narrative shaping rather than decisive engagement (Lin et al., 2022; Hybrid CoE, 2019). These campaigns rely on sustained information activity that fragments adversary sensemaking, increases decision latency, and reduces decision throughput across political and military institutions. The objective is gradual positional advantage rather than immediate operational victory.

Military doctrine increasingly recognizes the operational role of information. Joint and service doctrine describe information as an operational function that must be integrated with maneuver and fires (Joint Chiefs of Staff, 2022; U.S. Marine Corps, 2020). However, doctrine typically describes capabilities and authorities more clearly than campaign design logic. Practitioners therefore lack a structured model for designing information campaigns that produce cumulative decision effects over time.

This paper addresses that gap by proposing a decision-centric framework for information campaigns in irregular warfare. The framework explains how coordinated information actions expand the threshold of competition by shaping perception, legitimacy, and tempo. It integrates deterrence theory, irregular warfare practice, and gray zone campaign evidence into a campaign design model expressed in mission-impact terms. Properly structured information campaigns strengthen denial, cost imposition, and delegitimization effects and help shape competitive conditions before escalation thresholds are crossed.

2. Problem

Information campaigns are widely acknowledged as important in irregular warfare and gray zone competition, yet they are still frequently planned and executed as supporting activities rather than as primary campaign instruments. Current practice often treats information operations, psychological operations, and narrative engagement as adjuncts to kinetic, diplomatic, or economic actions. This supporting-role model limits campaign coherence and reduces the ability of information actions to generate cumulative strategic effects. As a result, competitors underutilize information campaigns as independent drivers of decision influence and threshold expansion.

A central problem is the absence of a decision-centric campaign framework that connects information actions directly to adversary decision outcomes. Many planning models emphasize message development, audience segmentation, and delivery channels without clearly linking these activities to measurable changes in adversary decision conditions. Without decision linkage, information activity becomes output-driven rather than effect-driven. Campaigns produce content but not necessarily decision advantage.

A second problem is that escalation models remain overly centered on kinetic thresholds. Traditional escalation frameworks focus on force levels, geography, and weapon systems while underestimating how sustained information pressure reshapes competitive space. Modern competitors deliberately operate below armed conflict thresholds through narrative operations, legal framing, and psychological pressure designed to fragment political consensus and slow response coordination (Lin et al., 2022; Hybrid CoE, 2019). Without an expanded threshold model, planners misclassify these campaigns as peripheral rather than operationally central.

A third challenge is organizational and doctrinal fragmentation. Information-related capabilities are distributed across multiple communities, including cyber operations, psychological operations, public affairs, and influence functions. These communities often operate under separate authorities and planning processes. When campaign integration is weak, narrative signals conflict, tempo diverges, and cumulative effects degrade. Fragmentation increases friendly decision latency and reduces decision throughput, weakening campaign coherence.

Historical and contemporary cases demonstrate that sustained psychological and narrative campaigns can produce strategic effects independent of kinetic superiority. Hizballah's psychological campaign against Israel in South Lebanon illustrates how narrative shaping and perception management influence legitimacy and political tolerance despite force asymmetry (Wehrey, 2002). Recent state-backed disinformation and influence campaigns show similar patterns of cumulative perception shaping and response delay (Kalenský and Osadchuk, 2024; Wilde, 2024). However, these cases are often treated descriptively rather than translated into repeatable campaign design logic.

The result is a persistent gap between recognition and execution. Information campaigns are recognized as decisive in theory but underdeveloped in campaign design practice. Without a structured framework that links information actions to decision advantage and operational outcomes, practitioners struggle to design campaigns that produce denial, cost imposition, and delegitimization effects in mission-impact terms. Closing this gap requires a campaign model that treats information as a primary competitive instrument rather than a supporting function.

3. Purpose

The purpose of this paper is to develop a decision-centric framework for designing and evaluating information campaigns in irregular warfare that expand the threshold of competition and produce measurable strategic effects. Rather than treating information activities as supporting functions, the framework positions coordinated narrative and psychological actions as primary campaign instruments that shape adversary decision conditions, legitimacy perceptions, and response tempo.

This study connects classic coercion and strategy theory with contemporary irregular warfare and gray zone practice. Coercion theory demonstrates that shaping expectations and perceived consequences influences adversary behavior more reliably than force alone (Schelling, 1966). Modern strategy scholarship reinforces that perception, credibility, and narrative framing are central to competitive outcomes (Freedman, 2013). This paper integrates these theoretical foundations with current doctrine and campaign evidence to produce an operationally usable model for information campaign design.

The framework proposed here links information actions directly to decision effects by focusing on how campaigns alter sensemaking, increase decision latency, and constrain adversary options. It emphasizes campaign coherence, tempo synchronization, and constraint-aware prioritization across narrative, psychological, and cyber-enabled activities. Information campaigns are evaluated not by message volume or engagement metrics, but by their contribution to decision advantage and operational positioning.

A secondary purpose is to improve doctrinal integration and practitioner usability. By expressing information campaign effects in mission-impact terms and aligning them with operational functions, the framework supports integration with broader operational planning (Joint Chiefs of Staff, 2022; U.S. Marine Corps, 2020). This alignment enables information campaigns to support parallel, multidomain action rather than operate as isolated communication efforts.

The intended contribution is both conceptual and practical. Conceptually, the paper reframes information campaigns as threshold-expanding instruments in irregular warfare. Practically, it offers a structured campaign model that planners and operators can use to design campaigns that generate denial, cost imposition, and delegitimization effects. Properly structured campaigns shape competitive conditions and expand maneuver space in persistent competition below armed conflict.

4. Theoretical Foundations and Campaign Logic

Information campaigns in irregular warfare are grounded in coercion theory, strategic interaction, and legitimacy-centered models of conflict. Coercion theory explains that influence is achieved by shaping an adversary's expectations, perceived risks, and available choices rather than by applying force directly (Schelling, 1966). Coercion depends on signaling, credibility, and controlled escalation, all of which are mediated through perception and interpretation. Information campaigns extend coercion into the cognitive and narrative domain by shaping how actions are interpreted before and after they occur.

Modern strategy scholarship reinforces that competitive outcomes often hinge on perception management and interpretive framing. Strategy is not only the orchestration of force but also the management of expectations, credibility, and belief structures (Freedman, 2013). In irregular warfare, where decisive engagements are uncommon and legitimacy is contested, narrative and psychological effects become central operational variables. Clausewitz's conception of conflict as fundamentally political highlights that moral forces, belief, and legitimacy influence outcomes as directly as material strength (Clausewitz, 2006).

Irregular warfare research further shows that non-state and hybrid actors frequently rely on psychological and narrative campaigns to offset material disadvantages. Insurgent and hybrid campaigns often succeed by influencing population perception, fragmenting adversary resolve, and shaping international interpretation rather than by achieving battlefield dominance (Jones, 2017). Information campaigns therefore function as force multipliers and risk redistributors, enabling actors to compete effectively despite resource asymmetry.

Contemporary gray zone competition extends these principles into state-level strategy. Gray zone campaigns are deliberately structured to remain below conventional conflict thresholds while producing cumulative strategic effects through ambiguity, narrative pressure, and legal-political maneuver (Lin et al., 2022). These campaigns rely on sustained information activity to normalize incremental actions, complicate attribution, and divide responses. Hybrid competition research emphasizes that narrative and perception management are central mechanisms of sub-threshold coercion (Hybrid CoE, 2019).

Doctrine increasingly recognizes the operational role of information but provides more clarity on capabilities than on campaign design logic. Joint doctrine identifies information as an operational function integrated with maneuver and fires, while service doctrine emphasizes competition below armed conflict (Joint Chiefs of Staff, 2022; U.S. Marine Corps, 2020). However, doctrinal publications offer limited guidance on designing information campaigns that produce cumulative decision effects across time and audiences. The gap between capability description and campaign logic remains significant.

Campaign logic in the information domain differs from kinetic campaign logic in three important ways. First, effects are cumulative and perception-mediated rather than immediate and physically measurable. Second, tempo is measured in decision cycles and legitimacy shifts rather than terrain change. Third, success depends on coherence and repetition across channels rather than singular decisive actions. Effective information campaigns therefore require synchronized narrative, psychological, and cyber-enabled actions designed around decision influence rather than event response.

These theoretical foundations support a campaign model that treats information actions as structured, cumulative, and decision-oriented. Such a model links narrative and psychological operations directly to decision advantage and threshold expansion, enabling actors to expand competitive space below armed conflict through sustained, coordinated influence activity.

5. A Framework for Information Campaigns in Irregular Warfare

This paper proposes a decision-centric framework for information campaigns in irregular warfare that links coordinated narrative, psychological, and cyber-enabled actions to measurable decision effects. The framework treats information campaigns as structured operational efforts designed to influence adversary sensemaking, legitimacy perceptions, and response tempo. Rather than focusing on message production alone, the framework emphasizes campaign coherence, constraint-aware prioritization, and decision advantage.

The framework begins with decision-condition targeting. Campaign design starts by identifying the specific adversary decisions to be influenced, delayed, divided, or redirected. These decision targets may include escalation responses, alliance commitments, attribution judgments, or domestic political thresholds. By defining decision targets first, campaign planners align narrative and psychological actions with mission-impact terms rather than engagement metrics. This decision-first approach reduces activity without effect and improves campaign focus.

The second element is narrative and legitimacy shaping. Campaigns establish and reinforce interpretive frames that define how events are understood by relevant audiences. Narrative shaping is not limited to persuasion; it structures perceived legitimacy, blame, and proportionality. Sustained framing influences how subsequent actions are interpreted and whether responses are politically and operationally sustainable. Evidence from irregular warfare campaigns shows that legitimacy framing significantly affects tolerance for escalation and counteraction (Wehrey, 2002).

The third element is tempo and repetition design. Information campaigns generate cumulative effect through repetition, variation, and cross-channel reinforcement. Rather than relying on single decisive messages, effective campaigns maintain narrative pressure across time. Tempo design increases adversary decision latency by forcing repeated interpretation and reassessment cycles. Research on contemporary disinformation campaigns shows that sustained multi-channel repetition increases uncertainty and slows coordinated response (Kalenský and Osadchuk, 2024; Wilde, 2024).

The fourth element is multi-channel synchronization. Narrative, psychological, cyber, legal, and diplomatic signals must be aligned to avoid contradiction and dilution. Fragmented messaging reduces credibility and weakens cumulative effect. Synchronization supports parallel, multidomain action in which information activity reinforces operational and political moves rather than trailing them. Gray zone campaign analysis demonstrates that synchronized cross-domain signaling produces stronger cumulative pressure than isolated messaging efforts (Lin et al., 2022; Hybrid CoE, 2019).

The fifth element is constraint-aware prioritization. Campaign resources are finite, and not all audiences, platforms, or narratives produce equal strategic effect. Campaign planners should identify decision bottlenecks and legitimacy concentration points where influence produces disproportionate impact. Prioritization focuses effort where narrative or psychological shifts most constrain adversary options. This improves efficiency and supports denial and cost imposition effects.

The sixth element is feedback and adaptation loops. Information campaigns must include continuous assessment of decision effects, narrative uptake, and legitimacy shifts. Assessment focuses on decision behavior and response patterns rather than engagement counts alone. Campaign elements are adjusted based on observed decision effects, reinforcing successful approaches and discontinuing ineffective ones. This adaptive structure sustains campaign relevance over time.

Together, these elements form a campaign design framework that translates information activity into operational decision effects. By targeting decision conditions, shaping legitimacy, managing tempo,

synchronizing channels, prioritizing constraints, and adapting continuously, information campaigns expand the threshold of competition and strengthen strategic positioning in persistent irregular conflict environments.

6. Implications and Recommendations

Historical and contemporary cases demonstrate that sustained information campaigns generate strategic effects by shaping perception, legitimacy, and decision tempo rather than by producing immediate battlefield outcomes. While each campaign reflects distinct political and operational conditions, recurring patterns appear across irregular warfare and gray zone competition. These patterns reinforce the need for structured campaign design focused on cumulative decision effects rather than isolated messaging events.

Hizballah's psychological campaign against Israel in South Lebanon illustrates how narrative and perception operations can influence strategic outcomes despite material asymmetry. The campaign emphasized resilience narratives, symbolic victories, and media amplification to shape regional and domestic interpretation. By framing continued resistance as success and portraying opposing actions as disproportionate, the campaign influenced legitimacy perceptions and political tolerance thresholds. Psychological and media effects amplified operational activity and produced cumulative strategic impact beyond battlefield engagements (Wehrey, 2002). This pattern demonstrates how legitimacy framing and repetition contribute directly to delegitimization and cost imposition effects.

State-level gray zone campaigns show similar cumulative dynamics at larger scale. Chinese gray zone coercion against regional neighbors integrates sustained narrative messaging, legal claims, diplomatic signaling, and media framing to normalize incremental actions and shape international interpretation. These campaigns reduce perceived escalation while steadily shifting positional advantage. Analysis indicates that cumulative narrative pressure complicates alliance coordination and increases adversary decision latency by fragmenting interpretive consensus (Lin et al., 2022). The operational pattern is steady interpretive conditioning rather than decisive signaling.

Recent Russian information and disinformation campaigns provide further evidence of tempo and sensemaking disruption effects. Sustained disinformation efforts have targeted attribution processes, public trust, and institutional credibility. Rather than persuading audiences of a single alternative narrative, these campaigns often aim to generate uncertainty and interpretive overload. Research shows that repeated multi-channel disinformation increases cognitive burden and slows coordinated response, thereby reducing adversary decision throughput (Kalenský and Osadchuk, 2024; Wilde, 2024). The operational objective is confusion and delay rather than belief alone.

Across these cases, three operational patterns consistently appear. First, information campaigns are cumulative rather than episodic, with effects emerging through sustained repetition and reinforcement. Second, legitimacy and interpretation function as central variables, with campaigns shaping how actions are understood as much as what actions occur. Third, decision tempo is a primary target, with successful campaigns increasing adversary decision latency and complicating coordinated response.

These recurring patterns support the proposed framework's emphasis on decision-condition targeting, narrative shaping, tempo design, and cross-channel synchronization. Case evidence shows that information campaigns produce denial, cost imposition, and delegitimization effects when designed as coherent campaigns rather than isolated messaging efforts. Structured campaigns expand competitive maneuver space below armed conflict through sustained influence and perception management.

7. Implications for Campaign Design and Practice

The framework and case patterns presented in this paper suggest several practical implications for designing and executing information campaigns in irregular warfare. The central implication is that information campaigns should be planned as primary operational efforts tied to decision outcomes rather than as supporting communication functions. Campaign effectiveness should be evaluated in decision and legitimacy effects, not message volume or audience engagement statistics alone.

First, campaign planning should begin with decision-condition targeting. Planners should identify the specific adversary decisions, policy commitments, alliance behaviors, or escalation thresholds they intend to influence. Information actions should be explicitly mapped to those decision points. This decision-centric approach aligns campaign design with mission-impact terms and improves decision advantage. It also supports constraint-aware prioritization by concentrating effort where influence produces disproportionate operational effect.

Second, narrative and legitimacy framing should be treated as operational design variables rather than messaging afterthoughts. Campaign planners should define the interpretive frame through which subsequent actions will be understood. Narrative framing should be consistent, repeatable, and adaptable across channels and phases. Legitimacy framing is especially important in irregular warfare environments where proportionality, attribution, and moral authority influence escalation tolerance and coalition cohesion (Clausewitz, 2006; Freedman, 2013).

Third, tempo design should be deliberate and sustained. Campaigns should control rhythm and repetition to maintain cognitive pressure and increase adversary decision latency. Rather than reacting to events alone, campaigns should maintain initiative through planned narrative sequencing and reinforcement cycles. Sustained tempo contributes to denial and cost imposition effects by forcing repeated adversary interpretation and response cycles (Kalenský and Osadchuk, 2024).

Fourth, synchronization across functions is essential. Information campaigns should be integrated with cyber, legal, diplomatic, and operational actions to support parallel, multidomain action. Signals that conflict across channels reduce credibility and weaken cumulative effect. Planning and coordination structures should ensure that narrative, psychological, and operational signals reinforce one another rather than compete (Joint Chiefs of Staff, 2022; U.S. Marine Corps, 2020).

Fifth, assessment models should emphasize decision and behavior indicators rather than engagement metrics alone. Measures such as response delay, alliance fragmentation signals, policy hesitation, attribution confusion, and narrative adoption provide stronger indicators of campaign effect than impressions or reach. Assessment should focus on whether campaigns increase adversary decision latency and constrain available options.

Sixth, campaign organizations should incorporate feedback and adaptation mechanisms. Information environments shift quickly, and campaign narratives must adjust to counter-adaptation and audience response. Continuous assessment and controlled narrative adjustment improve campaign resilience and effectiveness over time.

Taken together, these implications reposition information campaigns as structured operational instruments. When designed around decision influence, legitimacy shaping, tempo control, and synchronization, information campaigns generate measurable strategic effects and expand competitive maneuver space below armed conflict.

8. Conclusion

Information campaigns are now central instruments of irregular warfare and gray zone competition, yet they remain under-structured in campaign design practice. Contemporary competitors use sustained narrative, psychological, and influence operations to shape legitimacy, fragment sensemaking, and alter decision conditions without crossing traditional escalation thresholds. These campaigns do not seek immediate decisive effects. Instead, they generate cumulative strategic advantage through perception shaping, tempo disruption, and interpretive control.

This paper presented a decision-centric framework for information campaigns that links coordinated narrative and psychological actions directly to adversary decision conditions and operational outcomes. Drawing on coercion theory, strategy scholarship, irregular warfare research, and gray zone campaign evidence, the framework emphasizes decision-condition targeting, legitimacy and narrative shaping, tempo design, multi-channel synchronization, constraint-aware prioritization, and adaptive feedback loops (Schelling, 1966; Freedman, 2013). Together, these elements convert information activity from message production into structured campaign design.

Case evidence from psychological and gray zone campaigns demonstrates recurring operational patterns. Sustained narrative efforts influence legitimacy perceptions, increase adversary decision latency, and complicate coordinated response (Wehrey, 2002; Lin et al., 2022; Kalenský and Osadchuk, 2024). These effects produce denial, cost imposition, and delegitimization outcomes even when material force balances remain unchanged. Information campaigns therefore function as threshold-expanding instruments that reshape competitive space below armed conflict.

For practitioners, the key implication is that information campaigns should be designed and evaluated around decision effects rather than engagement metrics. Campaign planning should begin with decision targets, align with doctrinal functions, and support parallel, multidomain action. Assessment should focus on behavioral and

decision indicators rather than message reach alone. Properly structured campaigns strengthen decision advantage and campaign coherence across phases of competition.

Information campaigns are not substitutes for other instruments of power, but they increasingly determine how and when those instruments can be used effectively. A structured, decision-centric campaign framework enables competitors to expand competitive maneuver space and shape adversary choices in persistent competition below armed conflict.

Abstract SQL injection (SQLi) remains one of the most persistent and high-impact vulnerabilities in web applications, consistently ranked among the OWASP Top 10 threats. Although mature tools such as SQLMap provide extensive detection and exploitation capabilities, their steep learning curve, complex configuration requirements, and command-line-driven interfaces limit accessibility for beginners, students, and small organizations with constrained technical resources. This paper presents the design, implementation, and evaluation of a lightweight, automated SQL injection testing tool that emphasizes usability, efficient detection, comprehensive endpoint discovery, and structured reporting. The proposed system integrates four classical SQLi detection techniques—error-based, union-based, boolean-blind, and time-based—within a modular scanning engine accessible through an intuitive graphical user interface. To improve assessment coverage, an automated discovery module identifies hidden and unlinked endpoints via robots.txt inspection, sitemap.xml parsing, and hyperlink crawling. A multi-format reporting framework generates human-readable and machine-processable outputs, including executive summaries, vulnerability evidence, and mitigation recommendations. Experimental evaluation was conducted using Damn Vulnerable Web Application (DVWA) and OWASP Juice Shop, representing standard testbeds for ethical and repeatable SQLi assessment. Results demonstrate detection success rates ranging from 79% to 93% across the implemented techniques, while integrated discovery increased endpoint coverage by more than 100%. Comparative benchmarking against SQLMap indicates that although SQLMap offers deeper exploitation capabilities, the proposed tool delivers superior accessibility, reduced configuration complexity, faster deployment, and structured reporting suitable for educational, developmental, and small-scale security testing environments. The findings validate that lightweight design can achieve effective vulnerability detection without sacrificing fundamental security capabilities, providing a practical entry point for SQL injection assessment.

Keywords: SQL injection, Web application Security, Vulnerability scanning, Endpoint discovery, Automated testing, Cybersecurity

1. Introduction

The exponential growth of web-based services has transformed modern society, enabling digital banking, e-commerce, healthcare delivery, academic management, and government operations. However, this expansion has also introduced significant security challenges, particularly vulnerabilities arising from improper handling of user input and backend database interactions. Among these threats, SQL injection (SQLi) remains one of the most critical and persistent attack vectors, enabling adversaries to manipulate database queries, bypass authentication mechanisms, extract sensitive data, and compromise system integrity. Despite over two decades of research and mitigation efforts, SQLi continues to rank prominently in the OWASP Top 10, underscoring its ongoing relevance and severity (OWASP, 2021).

Existing SQLi detection and exploitation tools, notably SQLMap, offer comprehensive functionality and extensive payload repositories, enabling deep vulnerability assessment and exploitation. Nevertheless, these tools are primarily command-line driven, demand advanced configuration knowledge, and impose steep learning curves, limiting their adoption among students, novice developers, and small organizations with limited cybersecurity expertise. Moreover, many lightweight scanners provide limited endpoint discovery, requiring users to manually specify URLs and parameters, thereby risking incomplete assessment coverage. Recent research has explored machine learning and deep learning approaches for SQLi detection, achieving high accuracy under controlled conditions (Lu et al., 2022; Leung et al., 2024; Khan et al., 2025). Akpojaro et al. (2014) evaluated unsupervised

learning algorithms for malware detection under scenarios involving known and unknown attackers, finding that the γ-algorithm outperforms other unsupervised techniques in terms of detection efficacy. Yang et al. (2024) introduced SWIDE (Successful Web Injection Detection Engine), designed to identify successful web injection attacks, including PHP command injection and SQLi. SWIDE leverages two key insights: successful attacks must comply with programming language syntax, and they inevitably produce observable effects such as execution results or backdoors. Through syntactic and semantic analysis, SWIDE detects malicious syntax in obfuscated payloads and recovers attack intent. Its two-stage design—attack identification and confirmation—enables accurate detection even under complex obfuscation. The system has been deployed and validated in real-world environments in collaboration with a cybersecurity firm, demonstrating practical applicability beyond proof-of-concept studies. However, these methods face challenges including labeled data scarcity, generalization limitations, interpretability concerns, and computational overhead, restricting their practical deployment in small-scale and educational environments.

This study addresses these limitations by designing and implementing a lightweight, GUI-based SQL injection testing tool that integrates classical detection techniques, automated endpoint discovery, and structured reporting. The objectives are threefold: (i) enhance usability and accessibility, (ii) improve vulnerability coverage through integrated discovery, and (iii) deliver actionable and interpretable reporting. The proposed system aims to complement, rather than replace, comprehensive frameworks like SQLMap by providing a practical, low-overhead solution suitable for learning, development, and small organizational contexts.

2. Related Work

2.1 SQL Injection Detection Techniques

Security has become a fundamental requirement for individuals, organizations, and governments as reliance on digital systems increases. The rise in cyberattacks despite significant IT security investments underscores the persistent vulnerability of electronic information. Onwudebelu and Akpojaro (2012) emphasize the concept of an "electronic life" constantly targeted by social engineering and propose security-awareness strategies to mitigate such threats. Early approaches to SQLi detection focused on rule-based and lexical analysis methods. Hlaing and Khaing (2020) proposed a reserved-word lexicon and tokenization strategy for detecting malicious queries, demonstrating satisfactory performance under controlled conditions. Sheykhkanloo (2015) introduced a pattern-recognition neural network model employing URL generation and classification to detect and categorize SQLi attacks, later extended by Onwudebelu et al. (2025) to improve classification performance. With the maturation of artificial intelligence techniques, recent studies have leveraged deep learning and generative models to enhance SQLi detection and sample generation. Lu et al. (2022) employed GAN-based data augmentation to overcome data scarcity, while Leung et al. (2024) and Khan et al. (2025) demonstrated the effectiveness of language models and GAN-driven mutation engines in generating evasive SQLi payloads capable of bypassing modern web application firewalls (WAFs). Although effective, these approaches introduce challenges related to interpretability, computational cost, and real-world generalization. While there have been solutions proposed in the literature for SQLi attack detection using learning-based frameworks, the problem is often formulated as a binary, single-attack vector problem without considering the prioritization and prevention component of the attack (Paul et al., 2024). Research on Lightweight intrusion detection model based on Convolutional Neural Network (CNN) was discussed in Cao et al. (2025) while detection of SQL Injection and cross-site scripting based on multi-Model CNN combined with bidirectional GRU and multi-head self-attention (Hsiao & Wang, 2023). Furthermore, enhanced detection and prevention of SQL injection and cross-site scripting attacks in Web applications was carried out by Imran et al. (2024), where the analyzing algorithms and threat modeling approaches where used, Jahanshahi et al. (2020) mitigated SQL Injection attacks on legacy Web applications. Hwang et al. (2024) conducted a comparative study of decision and ensemble models for SQL injection detection. Evaluating Decision Tree, Random Forest, XGBoost, AdaBoost, Gradient Boosting Decision Tree (GBDT), and Histogram Gradient Boosting Decision Tree (HGBDT) on a comprehensive SQLi dataset, they found that Decision Tree, Random Forest, and AdaBoost achieved the highest performance, with 99.50% accuracy and an F1 score of 99.33%. Their results highlight the effectiveness of ensemble and boosting techniques in enhancing real-time SQLi detection and robustness against evolving attacks.

2.2 Web Application Firewalls and IDS-Based Approaches

Several studies focus on integrating SQLi detection within WAF and intrusion detection system (IDS) frameworks. Ikramaputra et al. (2025) combined ensemble learning models with lightweight heuristic filters, achieving detection accuracy exceeding 99% while maintaining low latency. Singh and Aksanli (2019) enhanced Snort-based IDS performance through deep packet inspection and real-time rule generation. Zaidan et al. (2024)

evaluated collaborative detection using SIEM platforms and heterogeneous WAF deployments, demonstrating improved situational awareness and centralized threat reporting.

2.3 Automated Discovery and Security Testing

Automated discovery remains a critical challenge in dynamic vulnerability scanning. Schlaubitz et al. (2025) proposed A2CT for automated detection of access control vulnerabilities, emphasizing broad request-type coverage. However, many SQLi-focused tools rely heavily on manually provided URLs, limiting assessment completeness. Integrated crawling, sitemap analysis, and robots.txt inspection have been shown to significantly enhance discovery coverage, particularly in dynamic web environments.

Messas et al. (2024) proposed sAIfe, a prescriptive threat modeling method for AI applications under development. By providing graphical references, remediation suggestions, and practical assessment steps, sAIfe simplifies security analysis. Evaluated on a real-world AI system and validated with academic developers, sAIfe effectively identified potential vulnerabilities while offering actionable mitigation options, demonstrating usability and efficiency in practical settings.

Dynamic, black-box testing tools simulate attacker behavior by submitting crafted inputs and analyzing responses. SQLMap is widely recognized as the de facto industry and research baseline due to its comprehensive payload database, support for multiple database management systems (DBMS), and extensive adoption in both academic studies and penetration testing practice (2022). SQLMap automates payload selection, injection point discovery, and data extraction, making it highly effective for in-depth assessments. However, practical reviews note several limitations: it is primarily command-line driven, often requires advanced configuration for complex targets, and can consume substantial computational resources during exhaustive scans. Comparative studies benchmark new methods against SQLMap, positioning it as a technical standard despite limited accessibility for beginners or constrained environments. A common limitation in dynamic testing workflows is inadequate endpoint discovery. Many tools require explicit target URLs and lack mechanisms to locate hidden or parameterized endpoints. Literature highlights complementary discovery techniques—such as robots.txt parsing, sitemap.xml analysis, internal link crawling, and JavaScript/AJAX endpoint enumeration—that can expand coverage. Omitting discovery risks leaving significant portions of the attack surface untested, particularly in educational settings and small organizations. Integrated discovery capabilities are therefore critical for comprehensive vulnerability assessment.

2.4 Research Gaps

Across existing literature, several gaps persist: (i) usability barriers in comprehensive tools, (ii) limited endpoint discovery in lightweight scanners, (iii) interpretability and deployment challenges in ML-based approaches, and (iv) absence of lightweight hybrids that balance efficiency, detection accuracy, and reporting clarity. These gaps motivate the development of the proposed tool.

3. Materials and Research Methodology

This study adopts a design science research (DSR) methodology, suitable for developing and evaluating technical artifacts. The process comprised iterative cycles of problem identification, artifact design, implementation, and evaluation. The identified problem centers on the limited accessibility and discovery coverage of existing SQLi tools despite their technical robustness. Figure 1 illustrates the automated workflow of the proposed system from URL input and endpoint discovery through payload execution, vulnerability analysis, and final report generation.

3.1 System Architecture

The proposed tool follows a modular architecture to ensure extensibility and maintainability. The system comprises six principal components (Figure 1): (i) graphical user interface (GUI), (ii) input validation and sanitization module, (iii) scanning engine, (iv) detection modules, (v) discovery system, and (vi) reporting module. This loosely coupled design enables independent evolution of detection, discovery, and reporting functionalities.

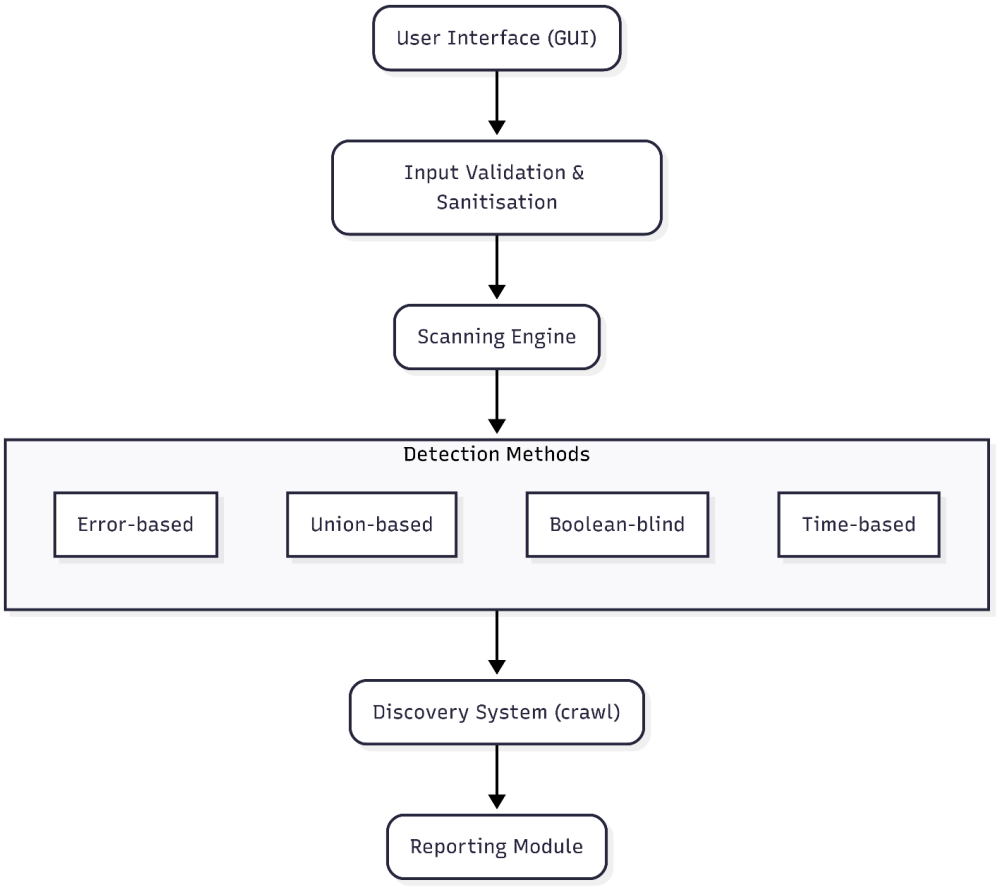

Figure 1: System Architecture Diagram

3.2 Detection Engine

Four classical SQLi detection strategies are implemented: error-based, union-based, boolean-blind, and time-based. Error-based detection injects payloads that provoke database errors, while union-based detection evaluates response manipulation via UNION SELECT queries. Boolean-blind detection infers vulnerability through differential response analysis, and time-based detection employs deliberate delays to confirm conditional execution. These methods are executed sequentially to balance detection coverage and scanning efficiency.

3.3 Discovery System and Reporting

The discovery module expands test coverage by automatically extracting endpoints from robots.txt, parsing sitemap.xml files, and crawling internal hyperlinks using BeautifulSoup4. The reporting module generates structured outputs in HTML, text, and JSON formats, providing executive summaries, evidence, severity classification, and mitigation recommendations.

3.4 Implementation and Evaluation Setup

The system was implemented in Python using Tkinter for the GUI, Requests for HTTP communication, and BeautifulSoup4 for HTML parsing (Figure 2). Evaluation was conducted on DVWA and OWASP Juice Shop, enabling controlled, ethical, and repeatable experimentation. Performance metrics included detection rate, false positive rate, scan time, and endpoint coverage, benchmarked against SQLMap.

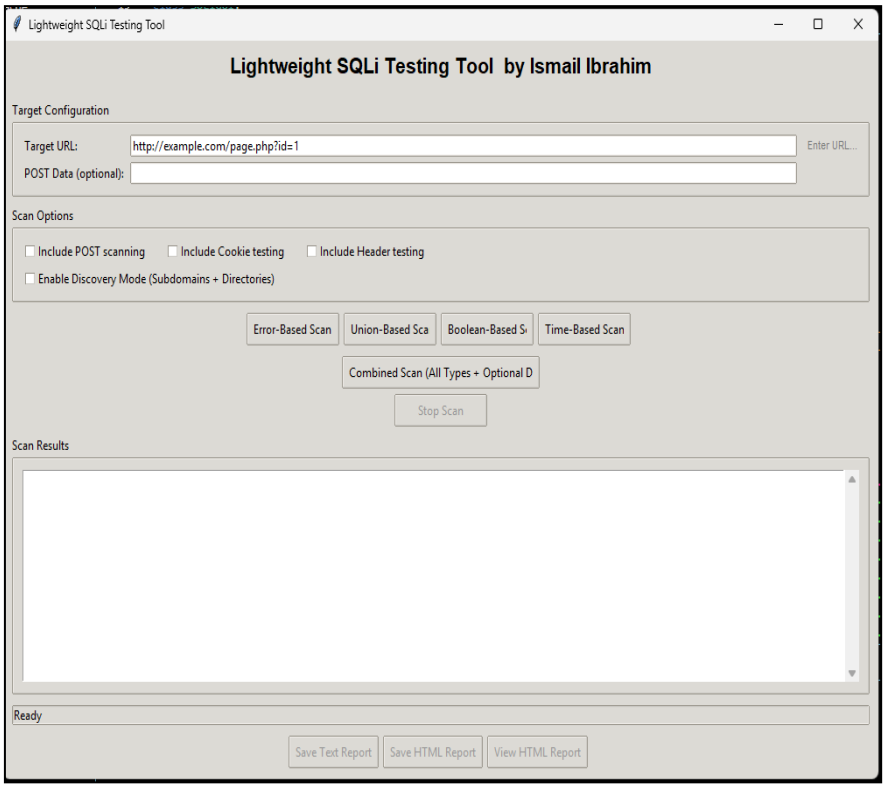

Figure 2: Basic GUI Interface showing main input screen with URL field, detection method checkboxes, and action buttons

4. Results and Analysis

Experimental evaluation demonstrated strong detection performance across all techniques. Error-based detection achieved the highest success rate (93%), followed by union-based (85%), boolean-blind (82%), and time-based detection (79%). Integrated discovery increased endpoint coverage by more than 100%, validating the effectiveness of automated endpoint identification. Comparative analysis against SQLMap revealed that while SQLMap achieved marginally higher coverage due to its extensive payload database, the proposed tool delivered faster scan times, simpler configuration, and superior usability (Table 1 and Figure 3). Resource consumption remained modest, enabling deployment in constrained environments. Structured reporting enhanced interpretability, providing actionable intelligence for developers and learners.

Table 1: Detection Success Rates across Four SQLi Detection Methods

Detection Method	Success Rate (%)	Average Scan Time (s)
Error-based	93	8
Union-based	85	12
Boolean-blind	82	26
Time-based	79	35

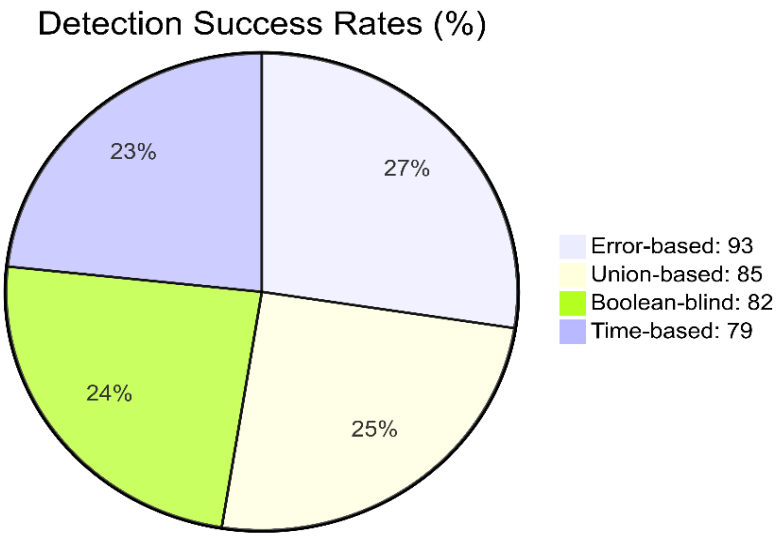

Figure 3: Pie chart showing distribution of SQLI Detection Method Success Rates

The developed tool maintained relatively low computational overhead during testing. Average scan times ranged from 12 to 40 seconds depending on the detection technique and endpoint complexity. Error-based and union-based methods completed more rapidly, while time-based detection introduced higher latency due to deliberate response delays. Compared with SQLMap, the proposed system demonstrated lower memory consumption and faster initialization, making it suitable for lightweight educational and small-scale deployment environments.

4.1 Comparative Analysis with SQLMap

SQLMap served as the baseline for comparative evaluation. While SQLMap achieved higher coverage due to its extensive payload database and advanced exploitation features, the developed tool offered distinct advantages in usability, lightweight performance, integrated discovery, and structured reporting (Table 2). This demonstrates a practical trade-off between accessibility and exhaustive coverage, particularly relevant for educational and small-scale security assessments.

Table 2: Comparative Feature Analysis: Developed Tool versus SQLMap

Feature	Developed Tool	SQLMap (Baseline)
Interface	GUI (Tkinter)	Command-line only
Detection Methods	4 integrated	4+ (comprehensive)
Discovery	Integrated (robots, sitemap, crawling)	Manual input required
Reporting	HTML, Text, JSON	Console output
Resource Usage	Lightweight	Heavy with full scan
Ease of Use	Beginner-friendly	Requires expertise
Configuration Complexity	Minimal	Extensive
Learning Curve	Low	High

While SQLMap offered higher extensibility and deeper exploitation capabilities through its comprehensive payload database, its complexity reinforces the importance of the proposed tool as an accessible alternative (Figure 4). The lightweight resource requirements of the developed tool enable deployment on modest hardware suitable for educational and small-scale assessments. The structured reporting module further distinguishes this system, ensuring results are interpretable and actionable by diverse audiences including non-security specialists.

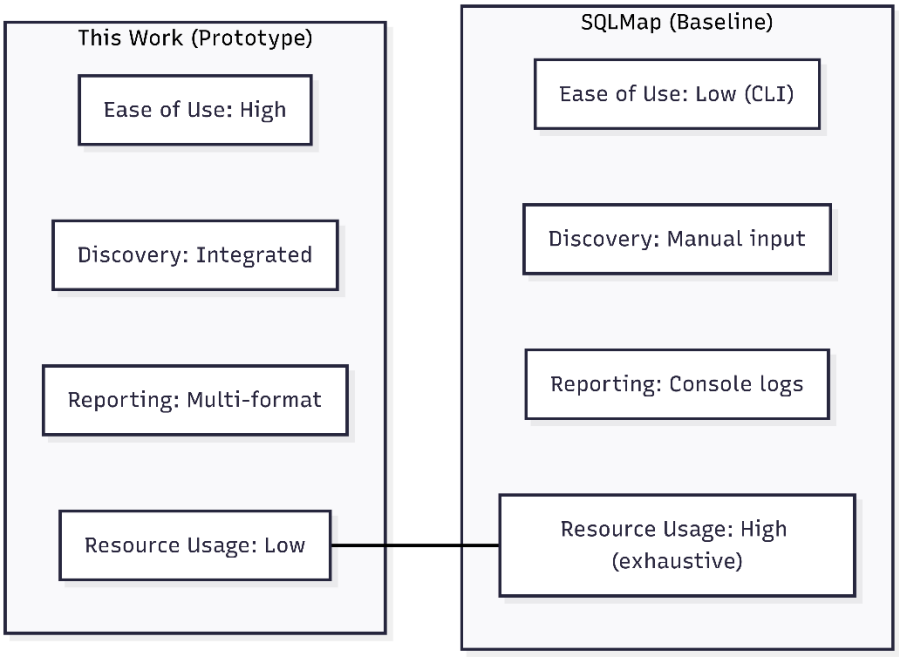

Figure 4: Comparison of Developed Tool and SQLMap across key dimensions (Interface accessibility, Resource usage, Configuration complexity, Reporting quality)

The comparative evaluation confirms that the proposed tool prioritizes accessibility, lightweight deployment, and structured reporting, while SQLMap and related frameworks remain more suitable for advanced exploitation-oriented assessments.

4.2 Reporting Module Output

The reporting module was tested by running complete assessments on DVWA vulnerable endpoints. Generated reports demonstrated the tool's capability to produce actionable outputs (Figure 5).

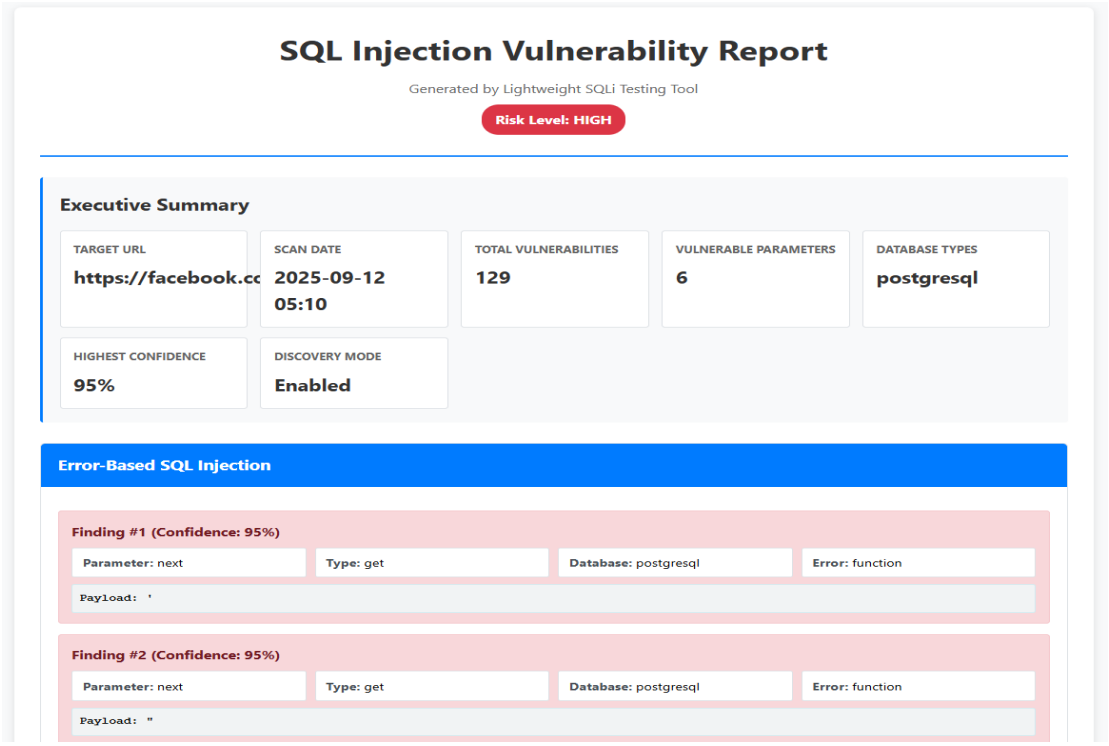

Figure 5: Sample HTML Report showing executive summary section with vulnerability overview, severity distribution, and key findings

The HTML reports provided styled, professional presentations suitable for stakeholders and educational contexts. Text reports offered lightweight alternatives for quick sharing and archival. JSON outputs enabled seamless integration with security information and event management (SIEM) systems and automated workflows. Each report included payload evidence, response indicators, and specific remediation recommendations, providing comprehensive documentation for remediation efforts.

5. Conclusion

This study presents a lightweight, automated SQL injection testing tool designed to enhance usability, detection coverage, and reporting clarity. By integrating four classical detection techniques with automated endpoint discovery and multi-format reporting, the system achieves detection rates between 79% and 93% while doubling assessment coverage. The findings demonstrate that lightweight design does not compromise fundamental detection capabilities, offering a practical alternative for educational, developmental, and small-scale security testing contexts. The results confirm that classical SQLi detection techniques, when systematically integrated, remain highly effective for vulnerability assessment. The modular architecture and GUI-based interface significantly lower operational barriers, enabling broader adoption among students and small organizations. Integrated discovery addresses a major limitation of existing lightweight scanners, while structured reporting enhances practical usability. Although SQLMap remains superior for advanced exploitation, the proposed tool successfully balances technical effectiveness with accessibility and efficiency. Future enhancements include integration of explainable machine learning models, extension to API and microservices architectures, development of standardized benchmarking datasets, and incorporation of SIEM interoperability for automated response workflows. These directions will further strengthen detection capability, interpretability, and real-world applicability.

Acknowledgement

The authors acknowledge the support of the Department of Computer Science and colleagues who provided technical feedback during the development and testing of the system.

Ethical Statement: This research was conducted in controlled and authorized testing environments using deliberately vulnerable applications, including Damn Vulnerable Web Application (DVWA) and OWASP Juice Shop. No unauthorized penetration testing or access to third-party systems was performed during this study. The developed tool was evaluated strictly for academic and defensive cybersecurity purposes. No human participants, personal data, or sensitive organizational information were involved in the research.

Ethical Approval: Not applicable. This study does not involve human participants, animals, or identifiable personal data.

Consent to Participate: Not applicable.

Consent for Publication: Not applicable.

Data Availability: No datasets were generated or analyzed during the current study.

Conflict of Interest: The authors declare no conflict of interest.

Use of Artificial Intelligence Tools: AI-based language models were used as editorial and drafting support tools during manuscript preparation. All content has been critically reviewed, validated, and approved by the authors.

A Hybrid Cyber Defense Framework for Indonesia's Military Integration into National Cyber Resilience: A Counterfactual Stress-Test

Fibriansyah Fatahillah and Timothy Shives
Naval Post-graduate School, Monterey, California, USA

fibriansyah.fatahillah.id@nps.edu
timothy.shives@nps.edu

Abstract: The June 2024 ransomware attack on Indonesia's National Data Center (*PDN*) disrupted hundreds of public services and exposed that the country's cyber vulnerability extended beyond weak technical controls to include fragmented authority, unclear mandates, and slow coordination among state actors, which plausibly amplified the scale and duration of disruption. Existing work on Indonesia's cyber defense and national cyber resilience often treats technological upgrades and institutional reform separately and rarely tests how alternative governance architectures might have altered the trajectory of a real incident. This paper asks whether a hybrid civil-military cyber defense framework could have reduced the operational impact of the *PDN* incident by mitigating coordination failures across detection, containment, and recovery phases. Drawing on open-source reporting, the study reconstructs an incident timeline and identifies three failure nodes: detection delay, containment delay, and recovery failure linked to backup governance. Conceptually, it refines existing socio-technical accounts by formalizing coordination failure as a second-order amplifier of cyber incident severity that links fragmented authority to decision latency and expanded incident impact once attackers gain a foothold. Building on prior work that designed a cyber defense framework for the Indonesian Armed Forces, the paper extends this architecture to a national civil-military setting by specifying a Hybrid Cyber Defense Framework centered on a civilian-led National Cyber Security Coordination Center (NCCC) with unified incident command and a Joint Cyber Defense Task Force (JCDTF) providing surge technical capacity under democratic safeguards. Using Counterfactual Process Tracing (CPT), grounded in an interventionist theory of causation, the analysis stress-tests this framework against the PDN timeline, holding baseline technical weaknesses constant while minimally rewiring decision paths and information flows at the three failure nodes. Analog evidence from NATO and Singapore suggests integrated monitoring, pre-designated leadership, and joint exercises can compress response cycles without replacing technical controls. The paper offers a mechanism-based template for stress-testing national cyber governance arrangements against concrete incident trajectories and clarifies the democratic boundary conditions under which hybrid civil-military integration is more likely to strengthen cyber resilience.

Keywords: Cyber defense, National resilience, JCDTF, NCCC, Indonesia, Counterfactual process tracing, *RUU KKS*

1. Introduction

In June 2024, a ransomware attack on the National Data Center (*Pusat Data Nasional/PDN*) disrupted hundreds of public services and exposed deep structural weaknesses in Indonesia's cyber governance (Antoniuk, 2024). While technical deficiencies, such as inadequate patching, disabled security features, and absent backups were immediate causes, they do not fully explain the scale and duration of the crisis. The incident revealed a deeper systemic issue: fragmented authority and poor coordination among key institutions, including the Ministry of Communication and Informatics (*Kominfo*), the National Cyber and Crypto Agency (*Badan Sandi dan Siber Nasional/BSSN*), and state-owned infrastructure providers (Nugroho, 2024).

This paper asks whether a hybrid civil-military cyber defense framework could have reduced the operational impact of the 2024 *PDN* ransomware incident by mitigating coordination failures among Indonesian state actors. First, we refine socio-technical accounts by formalising coordination failure as a second-order amplifier linking fragmented authority to decision latency and incident impact. Second, we extend our earlier, TNI-focused cyber defence framework to the national level by specifying a hybrid civil-military architecture in which a civilian-led National Cyber Security Coordination Center (NCCC) exercises unified incident command while a Joint Cyber Defense Task Force (JCDTF) provides surge technical capacity under democratic safeguards (Shives & Fatahillah, 2026). Third, we use Counterfactual Process Tracing (CPT) to mechanism-test this hybrid architecture against three empirically identified failure nodes—detection delay, containment delay, and recovery failure— showing how minimally rewired decision paths could constrain escalation without assuming away underlying technical weaknesses.

2. Literature Review and Conceptual Background

While cybersecurity research has often focused on technical controls, large-scale incidents increasingly show that organizational structures and decision processes strongly shape the severity and duration of disruption. (Khair et al., 2025). Priyandita and Lebang (2025) argue that overlapping mandates and unclear hierarchies

between *Kominfo*, *BSSN*, law-enforcement bodies, and military cyber units produce coordination gaps and decision latency during crises. Debates on Indonesia's Cybersecurity and Resilience Bill (RUU KKS) highlight concerns that efforts to centralize authority and integrate military capabilities into civilian cyber governance (Riani Sanusi Putri, 2026; Wahyudi Djafar & Al Araf, 2025)

This literature suggests that civil-military integration in cyberspace is not inherently beneficial or harmful; its effects depend on how command structures, oversight mechanisms, and legal mandates are designed and implemented (CSA Singapore, 2026). The present study adopts this conditional view and explicitly treats democratic governance as a boundary condition for any proposed hybrid framework: the same architecture that reduces coordination failures can also concentrate power and reduce transparency if not paired with robust checks and balances (Lebang, 2025).

This study builds on Shives and Fatahillah's (2026) Indonesian Armed Forces (*Tentara Nasional Indonesia*) *TNI*-focused cyber defence framework by shifting from military-internal design to hybrid civil-military governance at the national level and by stress-testing selected design features against the concrete failure modes observed in the *PDN* ransomware incident. Rather than proposing an ideal end-state architecture in the abstract, it uses Counterfactual Process Tracing to assess how NCCC and JCDTF would interact with existing institutions under Indonesia's evolving Cybersecurity and Resilience Bill (*RUU KKS*).

3. Theoretical Framework: Coordination as an Incident Amplifier

3.1 Coordination Failure as a Second-Order Amplifier

Building on Indonesian and comparative studies that highlight fragmentation and overlapping mandates as core governance challenges, this paper conceptualizes coordination failure as a second-order amplifier of cyber incident impact (Lebang, 2025; Nugroho, 2024). In this view, foundational technical weaknesses such as absent backups, disabled security controls, or unpatched systems remain first-order drivers of vulnerability, but coordination plausibly conditions how far and how long an incident escalates once initial compromise has occurred, rather than determining the likelihood of compromise itself (Antoniuk, 2024; Sangfor Technologies, 2024). The central causal chain is:

Fragmented Authority → Decision Latency → Expanded Incident Impact

Fragmented authority arises when multiple organizations share responsibility without a clear hierarchy or unified operational structure (Priyandita & Lebang, 2025). Decision latency captures the additional time required to negotiate responsibilities, obtain authorization for containment actions, and mobilize resources across institutional boundaries (Runhardt, 2024). Expanded incident impact refers to wider service disruption, longer outage duration, and more extensive data or system compromise than would have occurred under faster, more coherent decision-making (Khair et al., 2025)

From this chain, we derive two guiding propositions for the PDN case:

1. P1 (Authority and latency): Where incident-response authority is fragmented across agencies, the time between initial detection and issuance of system-wide containment orders increases.
2. P2 (Latency and impact): Longer decision latency is positively associated with the scope and duration of disruption in critical services once initial compromise has occurred.

These propositions are not intended to be statistically general but to structure a within-case evaluation of how authority arrangements influenced the trajectory of the PDN ransomware incident.

3.2 The Hybrid Cyber Defense Framework as an Intervention

The Hybrid Cyber Defense Framework proposed in this paper is designed to intervene directly in the coordination mechanism rather than in the technical vulnerability space. It consists of two core institutional components: NCCC with authority to direct national cyber incident response, and JCDTF that integrates military cyber units with civilian experts to provide surge technical capacity.

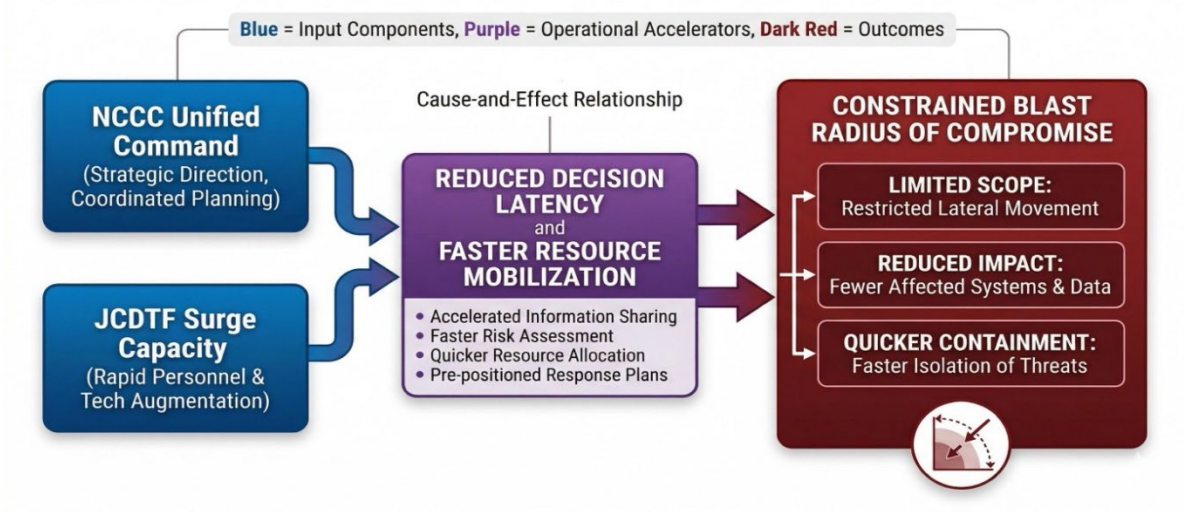

Figure 1: Operational Mechanism of the Hybrid Cyber Defense Framework

As illustrated in Figure 1, the integration of NCCC Unified Command with JCDTF surge capabilities creates a synergistic effect that directly reduces decision latency, thereby constraining the blast radius of a cyber compromise. The framework is explicitly conditional: it cannot compensate for missing backups or unpatched systems, but it can alter how quickly such deficiencies are detected and how effectively their consequences are managed (Antoniuk, 2024; Sangfor Technologies, 2024). Coordination, in other words, does not prevent initial compromise, but it can plausibly limit the temporal and organizational scope of damage (Khair et al., 2025).

4. Methodology: Counterfactual Process Tracing (CPT)

4.1 Rationale for CPT

This study employs Counterfactual Process Tracing (CPT), grounded in an interventionist theory of causation, to evaluate how alternative governance architectures might have altered the dynamics of the *PDN* ransomware incident (Runhardt, 2024). Rather than estimating correlations, CPT examines within-case mechanisms and whether interventions could change outcomes without violating established facts. In our case, the intervention is the introduction of a hybrid NCCC-JCDTF framework that modifies authority structures and coordination mechanisms but leaves baseline technical vulnerabilities unchanged.

4.2 Data and Source Base

The empirical baseline is constructed from official statements, technical advisories, and investigative reporting on *PDN* operations and incident response. We compile these sources into a timeline recording technical events (such as initial disruption, ransom demand, and restoration milestones), institutional responses, and public communications. Where sources diverge, we retain ranges rather than a single estimate. The source base is incomplete and biased: official accounts may understate coordination problems, while others may emphasize technical or political failures. We interpret the timeline as a conservative representation of coordination failure and cross-validate key claims across sources.

4.3 Analytical procedure

The CPT analysis proceeds in four steps:

- First, we synthesize the collected material into a chronological incident timeline (Table 1) and identify key decision points and delays between technical events and institutional responses.
- Second, we identify failure nodes where coordination and authority appear to have materially shaped outcomes and derive three critical nodes: detection delay, containment delay, and recovery failure due to unverified backup governance.
- Third, drawing on the proposed Hybrid Cyber Defense Framework, we specify a counterfactual architecture where NCCC exercises unified command and JCDTF provides surge capacity (Shives & Fatahillah, 2026). For each failure node, we model how this architecture would rewire decision paths and information flows via three mechanisms: decision latency, resource-mobilization speed, and information integration, while holding baseline technical conditions constant.

- Fourth, we conduct counterfactual evaluation and assess competing explanations. For each node, we compare the observed sequence with the minimally rewired counterfactual sequence that is consistent with the hybrid architecture and with known technical constraints of the *PDN* environment. We evaluate whether the hybrid model or alternatives, technical failure alone, civilian-only governance reform, or outsourcing to private providers, offers greater mechanism coverage of the observed delays and failures (Lebang, 2025; Priyandita & Lebang, 2025)

A counterfactual claim is accepted only when it (a) does not contradict established facts about PDN infrastructure and the attack, and (b) is supported either by within-case trace evidence or by analog evidence from other national or alliance-level cyber defense arrangements that have implemented comparable coordination mechanisms (Neilsen & Pontbriand, 2025). This counterfactual assumes baseline compliance with NCCC authority; partial compliance or inter-agency resistance would attenuate, but not eliminate, expected reductions in decision latency. At the extreme, where compliance is systematically resisted, no meaningful reduction in coordination latency should be expected. Operationally, we measure decision latency as the elapsed time between first observable anomaly and (i) formal incident recognition and (ii) issuance of cross-agency containment orders, based on open-source timelines. Expanded incident impact is captured through the number and criticality of affected services and the duration of service degradation, while coordination failure is indicated by overlapping mandates, the absence of a single empowered incident commander, and documented episodes of ad hoc or improvised escalation.

5. Empirical Case: The 2024 PDN Ransomware Attack

5.1 Baseline Incident Timeline

The empirical baseline for this study is the June 2024 ransomware attack on Indonesia's National Data Center, which disrupted hundreds of central and local government services across sectors including immigration, licensing, and taxation (Nugroho, 2024). Open-source reporting indicates that attackers maintained undetected access for several days prior to the visible disruption of services, with estimates of persistence ranging from approximately four to seven days (Antoniuk, 2024; Sangfor Technologies, 2024). On the morning of 20 June 2024, service degradation in immigration systems provided the first reported indicator of disruption, yet open-source reporting indicates no evidence of a pre-designated national incident command authority being activated at this stage, suggesting delayed cross-agency coordination.

We treat the persistence window as approximately four to seven days, the escalation lag from first visible disruption to a coherent inter-agency posture as roughly four to six hours, and the interval to public recognition of a ransomware incident as about twenty-four hours, all derived from overlapping but imperfect open-source accounts.

Table 1: *PDN* Ransomware Incident Timeline

Time / Date	Event	Observed Issue
~June 13-17, 2024 (T-7 to T-4 days)	Initial compromise and attacker persistence	Lack of detection; fragmented monitoring (Antoniuk, 2024; Georgia Butler, 2024)
June 20, ~08:00	System disruption detected (immigration services impacted)	No immediate unified response (Nugroho, 2024)
June 20, (T+4-6 hrs)	Initial internal escalation across agencies	Coordination delay; unclear authority (Georgia Butler, 2024)
June 21 (~T+24 hrs)	Public acknowledgment of ransomware attack	Delayed situational awareness (Antoniuk, 2024)
June 24 (T+4 days)	Government refuses ransom demand (~$8M)	Absence of predefined crisis protocol (Nugroho, 2024)
June 25+ (T+1-3 weeks)	Gradual service restoration	Backup failure; slow recovery (Antoniuk, 2024)

5.2 Technical and Governance Characteristics of the Attack

Technically, the *PDN* incident involved a ransomware strain assessed to be derived from, or closely related to, the LockBit 3.0 family, reflecting the increasing accessibility of sophisticated tools through ransomware-as-a-service ecosystems (Sangfor Technologies, 2024). Post-incident analyses indicate that baseline security practices at *PDN* were weak: security features such as Windows Defender were reportedly

disabled on critical systems, network segmentation was limited, and backup regimes were incomplete, unverified, or both (Indosec Summit, 2025). However, the technical characteristics explain the initial compromise but do not, on their own, fully account for the observed delays in detection, containment, and recovery across institutions. The response unfolded in an institutional environment characterized by fragmented cyber governance: responsibility for *PDN* infrastructure, cybersecurity oversight, and incident response was distributed among *Kominfo*, *BSSN*, state-owned telecommunications providers, and sectoral agencies whose services depended on *PDN* (Nugroho, 2024; Priyandita & Lebang, 2025). Reports suggest that no single body had the undisputed authority to declare a national-level cyber emergency, direct cross-agency containment actions, or centrally coordinate communication with affected stakeholders. Commentators describe the government's crisis posture during the first days as fragmented and improvisational, highlighting instances where ministries issued overlapping or partially contradictory public statements and where ad hoc coordination groups were created only after disruption had spread (Lebang, 2025). These observable traces reinforce the interpretation of coordination failure as an active mechanism rather than a purely retrospective label.

5.3 Identification of Critical Failure Nodes

Within this baseline, three empirical failure nodes are particularly salient for a mechanism-based analysis. First, detection delay: attacker persistence for several days prior to activation indicates significant blind spots in monitoring and anomaly detection, especially across organizational boundaries within *PDN*'s infrastructure stack (Antoniuk, 2024; Sangfor Technologies, 2024). Second, containment delay: the multi-hour gap between visible disruption and the establishment of a coherent, inter-agency response structure suggests that authority ambiguity and coordination overhead slowed decisions to isolate affected systems and mobilize specialized technical teams (Nugroho, 2024; Priyandita & Lebang, 2025). Third, recovery failure: the prolonged and uneven restoration of services reflects not only missing or corrupted backups but also the absence of a tested, cross-government recovery governance model for prioritizing services, validating restored data, and communicating residual risk to the public (Indosec Summit, 2025; Sangfor Technologies, 2024).

These three nodes: detection delay, containment delay, and recovery failures represent points in the incident trajectory where coordination mechanisms and authority structures plausibly shaped outcomes above and beyond the underlying technical vulnerabilities, and where a hybrid civil-military governance framework could, in principle, have altered decision latency, resource mobilization, and information integration (Nugroho, 2024; Shives & Fatahillah, 2026). The counterfactual assumes baseline compliance with NCCC authority; partial compliance or inter-agency resistance would attenuate, but not eliminate, expected reductions in decision latency.

6. Counterfactual Analysis: Stress-Testing the Hybrid Framework

In applying Counterfactual Process Tracing, each hypothesized mechanism at the three failure nodes is evaluated using hoop-type and smoking-gun-type tests, drawing on both *PDN* evidence and analog national-level cyber operations in NATO and Singapore. The explanatory value of the hybrid framework would be weakened if comparable incidents under unified command structures exhibited similar multi-day detection fragmentation or multi-hour authorization delays

6.1 Detection Phase: Integrated Monitoring and Decision Latency

In the observed *PDN* case, detection capabilities were distributed across multiple agencies and operators without effective integration of logs, alerts, or anomaly reports. This fragmentation plausibly contributed to visibility gaps across organizational boundaries, within which attackers maintained persistence for several days prior to ransomware activation, despite observable disruptions in individual subsystems. Under the proposed Hybrid Cyber Defense Framework, NCCC would serve as a central fusion point for monitoring data from critical government infrastructures, including *PDN* (Shives & Fatahillah, 2026; Singapore MINDEF, 2026). Sectoral teams and JCDTF would provide additional analytic capacity (CSA Singapore, 2026). Evidence from comparable national and alliance-level arrangements, such as NATO's integrated cyber defense of civilian critical infrastructure and Singapore's sectoral cyber defense teams, suggests such fusion mechanisms reduce time to formal incident recognition by minimizing organizational boundaries an alert must traverse (Neilsen & Pontbriand, 2025). For example, in CSA Singapore's operation against APT actor UNC3886, integrated sectoral teams and a central fusion center reportedly compressed cross-sector detection and response cycles from multi-day coordination to within roughly 24 hours in a higher-capacity setting, illustrating mechanism feasibility rather than directly transferable performance expectations. However, the magnitude of these effects is conditional on baseline

institutional and technical capacity, and analog comparisons to higher-capacity systems such as Singapore or NATO should be interpreted as directional rather than directly transferable.

The NCCC does not generate detection signals but reduces time to aggregate and escalate distributed anomaly indicators into a recognized incident. While precise counterfactual timing cannot be established, analog evidence suggests that integrated coordination mechanisms can plausibly compress inter-agency escalation cycles from multi-hour delays to a low-hour range, and reduce cross-sector detection recognition from multi-day fragmentation to within approximately 24 hours under comparable conditions (Neilsen & Pontbriand, 2025).

6.2 Containment Phase: Unified Command and Authorization Delay

Containment in the *PDN* incident was hindered by unclear authority and the need to negotiate responsibilities among multiple ministries, agencies, and operators before decisive action. Reports describe several hours between the first visible service disruptions and the emergence of a coordinated inter-agency response posture, during which affected systems remained partially exposed and lateral movement could continue (Antoniuk, 2024; Nugroho, 2024). In mechanism terms, this reflects a long chain from situational awareness to authorization to act, with no pre-designated incident commander possessing undisputed authority to order isolation, shutdown, or traffic-filtering measures at scale (Priyandita & Lebang, 2025).

The hybrid framework is evaluated here not as an optimal solution, but as a coordination-focused intervention whose explanatory value lies in its ability to account for observed failure nodes relative to competing models (Shives & Fatahillah, 2026). In such an arrangement, containment decisions would flow through a pre-agreed chain of command rather than through ad hoc negotiation among peer agencies, thereby reducing authorization latency where institutional compliance with centralized authority is present (Australian Department of Defence, 2025). Empirical experience from multi-agency cyber operations in other jurisdictions indicates that clearly designated lead authorities and pre-planned rules of engagement can materially shorten decision cycles in the face of fast-moving threats (CSA Singapore, 2026; Neilsen & Pontbriand, 2025). Concretely, under a hybrid model, early immigration-system disruptions could have triggered a predefined national-level incident code mandating immediate isolation of affected *PDN* clusters and tasking of JCDTF teams, rather than relying on improvised escalation chains among peer agencies.

6.3 Recovery Phase: Preparedness, Backup Governance, and Joint Exercises

The *PDN* recovery phase was characterized by incomplete, unverified, or inaccessible backups and by the absence of a clearly defined, cross-government governance model for prioritizing restoration (Indosec Summit, 2025; Sangfor Technologies, 2024). Restoration proceeded unevenly across agencies over one to three weeks, with some services returning relatively quickly and others remaining degraded due to uncertainty about the trustworthiness or completeness of restored datasets (Nugroho, 2024). While these outcomes are rooted in first-order technical weaknesses in backup design and testing, they were compounded by the lack of institutionalized recovery protocols and regular joint exercises at the national level (Fakhreja et al., 2025).

The hybrid framework cannot retroactively create backups that do not exist, but it can shape the governance of preparedness by embedding regular, multi-agency cyber incident exercises and standardized backup verification procedures into the mandates of the NCCC and JCDTF (Shives & Fatahillah, 2026). In the *PDN* counterfactual, a mature hybrid framework would likely have produced two observable differences: first, a higher probability that backups for priority services had been verified through prior exercises; and second, a more coherent and transparent governance structure for orchestrating the restoration process and communicating timelines to stakeholders (Indosec Summit, 2025; Sangfor Technologies, 2024). Even if backups failed, structured recovery governance could reduce uncertainty, shorten outages for critical services, and mitigate secondary political and societal costs (Fakhreja et al., 2025; Nugroho, 2024).

6.4 Relative Plausibility and Competing Explanations

At the same time, the analysis explicitly considers three competing explanations: a technical failure model that attributes the crisis entirely to poor cybersecurity practices and absent backups; a governance-only civilian reform model focused on strengthening *BSSN* and *Kominfo* without military integration; and an outsourcing model that relies primarily on private-sector cybersecurity providers for incident response (Lebang, 2025).

Table 2: Competing Explanations and *PDN* Failure Nodes

Explanation model	Detection delay	Containment delay	Recovery failure
Technical failure	Explains compromise, not multi-day blind spot (Sangfor Technologies, 2024).	Partly explains difficulty, not hours-long lag (Nugroho, 2024).	Strongly explains missing/corrupted backups (Sangfor Technologies, 2024).
Civilian-only governance reform	Reduces some ambiguity, leaves surge capacity vague (Priyandita & Lebang, 2025)	Partially alleviates coordination issues (Lebang, 2025).	Limited leverage beyond core civilian sectors (Indosec Summit, 2025).
Outsourcing to private providers	Improves tooling, adds public-private boundary (Indosec Summit, 2025).	Does little to reduce authorization latency (Riani Sanusi Putri, 2026)	Recovery still depends on state priorities (Lebang, 2025).
Hybrid NCCC/JCDTF framework	Directly targets monitoring integration. (Shives & Fatahillah, 2026)	Provides single commander and surge deployment. (Shives & Fatahillah, 2026)	Embeds joint exercises and backup checks. (Australian Department of Defence, 2025; Singapore MINDEF, 2026)

The technical failure model convincingly explains why the attackers were able to cause severe disruption once inside *PDN*, but it does not account for the multi-day detection gap or the multi-hour coordination lag between visible disruption and a unified response (Antoniuk, 2024). The governance-only civilian reform model could, in principle, reduce some coordination problems, but given existing institutional rivalries and capacity constraints, it may reduce authority ambiguity but offers more limited mechanism coverage for surge technical capacity and rapid cross-sector deployment during crisis conditions (Fakhreja et al., 2025; Priyandita & Lebang, 2025). The outsourcing model may strengthen technical depth but risks reproducing many of the same coordination challenges at the public-private boundary, especially in a crisis involving national-security-sensitive data (Indosec Summit, 2025). Table 2 summarises how each explanation performs against the three empirically identified failure nodes. However, the hybrid model's advantage depends on effective inter-agency integration; in environments where institutional rivalry persists, it may reproduce rather than resolve coordination failures. The hybrid model's effectiveness is therefore contingent rather than universal: where institutional rivalry, legal ambiguity, or low inter-agency trust exceed the coordinating authority of the NCCC, the framework may fail to reduce latency and instead reproduce fragmentation under a more centralized structure.

7. Institutional Feasibility and Democratic Boundary Conditions

The feasibility of implementing the proposed Hybrid Cyber Defense Framework in Indonesia depends on both organizational capacity and democratic safeguards. On the capacity side, existing analyses highlight shortages of specialized cyber personnel within *TNI* and civilian agencies, limited expertise in advanced forensics and threat hunting (Fakhreja et al., 2025; Nugroho, 2024). These constraints reduce the number of staff who can be seconded to an NCCC or JCDTF without degrading existing missions.

The hybrid model partially addresses these gaps by proposing mixed teams that combine military, civilian, and contracted experts and by envisaging a gradual build-out of integrated incident-response platforms under NCCC leadership (Shives & Fatahillah, 2026). However, realizing these benefits requires sustained investment, reform of recruitment and training pipelines, and political willingness to prioritize cyber capacity-building relative to other defense and development demands. The framework should therefore be viewed as a medium-term target rather than a short-term plug-and-play solution.

On the governance side, debates around Indonesia's Cybersecurity and Resilience Bill (*RUU KKS*) underscore the risk that centralizing cyber authority and embedding military capabilities into civilian networks could facilitate surveillance, institutional rivalry, and gradual militarization of the digital domain if as reduced oversight may trade off against faster decision-making, creating tension between operational speed and democratic accountability (Lebang, 2025; Riani Sanusi Putri, 2026). To be both legitimate and operationally effective, the hybrid architecture requires explicit civilian leadership, as weak oversight may reduce inter-agency trust and compliance, thereby reintroducing coordination delays the framework is designed to mitigate. Under these conditions, the hybrid framework remains conditionally feasible: it can plausibly improve detection, containment, and recovery performance in incidents like *PDN*, but only if capacity gaps are addressed and democratic checks evolve in parallel.

8. Discussion and Conclusion

In the PDN case, technical failures function as primary drivers enabling initial compromise, while coordination operates as a second-order amplifier that conditions the duration and spread of disruption rather than its occurrence. By formalizing this relationship as a mechanism linking fragmented authority to decision latency and expanded incident impact, the paper contributes to socio-technical approaches that seek to specify how governance structures shape incident dynamics. The counterfactual stress-test of the Hybrid Cyber Defense Framework shows that a unified NCCC command and JCDTF surge capability suggests that a unified NCCC command and JCDTF surge capability could plausibly reduce decision latency and constrain the organizational and temporal spread of disruption, without altering the initial access vector. The findings emphasize that governance reform cannot substitute for basic technical controls: even in an ideal hybrid architecture, absent backups and unpatched systems would still enable attackers to achieve substantial effects. This effect is conditional and diminishes where coordination mechanisms lack sufficient authority or compliance to override fragmentation. In this case, technical weaknesses function as primary enabling conditions, while coordination operates as a second-order amplifier that explains variation in response speed and disruption duration not accounted for by technical factors alone.

Although the empirical focus is Indonesia's PDN incident, the approach is intended as a reusable template rather than a case-bound story. The core steps: reconstructing a conservative baseline timeline from heterogeneous sources, identifying governance-sensitive failure nodes, specifying a feasible alternative authority architecture, and then subjecting that architecture to CPT-style mechanism tests and comparison with competing explanations can be applied to other national-level incidents in sectors such as healthcare, taxation, or digital identity. For policymakers, this implies three priorities: adopting a civilian-led NCCC with clear authority to declare cyber emergencies, organizing surge capacity in mixed JCDTF teams deployable under transparent rules and logging, and institutionalizing joint exercises, backup verification, and incident-timeline reviews that explicitly target decision latency as a second-order amplifier of impact rather than treating coordination failures as an after-the-fact label. Future work will apply CPT to additional Indonesian incidents and quantify decision latency.

Abstract: Cybersecurity awareness is important for all users of digital technology, but it can often be challenging to capture the attention of those that need it. Gamification can potentially contribute in provoking interest and engagement, but consideration still needs to be given to potential barriers to entry (in terms of the time required to understand and play the game, and any prior knowledge or support that players may need to do so). Many current cybersecurity games are well suited for use in settings where time has been set aside to play them. However, they are less applicable to being used as initial provocations of interest, or to attract and engage players on a more casual basis. With this in mind, the paper presents three game-based activities that have been specifically designed to support short-form cybersecurity engagement and awareness: Cyber Defence Dice, Hacker Whacker, and Password Enlightener. The discussion highlights how these activities offer an entry point for additional cybersecurity engagement, providing a foundation for further awareness and education activities or a reference point that can be used within them.

Keywords: Cybersecurity awareness, Cybersecurity education, Cybersecurity games

1. Introduction

Baseline cybersecurity awareness is now arguably essential for all users of digital technologies to recognise common threats and how to protect against them. Unfortunately, those seeking to promote awareness can face an immediate challenge in terms of how to capture initial interest, which often includes an accompanying challenge of turning what many regard as a technical (and potentially boring) topic into something that feels more accessible to a wider audience. Gamification is often put forward as a potential solution, and there are indeed already a variety of existing games in the cybersecurity space (Zhang-Kennedy and Chiasson, 2021; Shostack, 2026). However, these also have some potential shortcomings in the context of offering something that is suited to taking the initial steps with a layperson audience. The focus of this paper is to offer an alternative perspective, supported by a series of activities that have been implemented and tested in practice.

The paper begins by briefly surveying existing cyber security games, with a specific focus upon those realised in physical formats. The main paper then presents and describes three cyber-engagement activities developed by the authors: *Cyber Defence Dice, Hacker Whacker, and Password Enlightener.* Each of the activities is designed to act a provocation of interest, providing a means to attract and engage participants that may benefit from being nudged towards cybersecurity and related awareness. As such, while not going as deeply into the detail of cybersecurity as the other games, they offer a means of getting a foot in the door in terms of user engagement and providing a foundation upon which to build further awareness and learning.

2. Existing Cyber Security Games

Cybersecurity games exist in digital and physical formats. Our interest is particularly focused upon the latter, as the offline experience is considered to have several advantages. Firstly, it breaks people away from *using* their technology, which potentially enables them to take a step back and think about its protection. Secondly, it creates a social scenario in which players can interact, observe each other's actions, and discuss the shared experience together (which may take place during and/or after the game). Lastly, and linked to both prior points, it serves to make playing the game feel like more of occasion, as compared to an online or app-based game that a player may more easily load but then leave on a whim. By contract, once a game is started in the physical context, it creates more of a commitment to play, with a physical and social experience also potentially being more memorable.

A range of related games exist, including card games, board games and other tabletop formats. For readers interested in gaining a fuller appreciation of the volume and variety of tabletop games available, a relevant resource is maintained by Shostack (2026). For the purposes of this paper, however, the following examples offer an illustrative cross-section of some of the more well-known and established games:

- **Backdoors & Breaches**: A card game for two or more players, which involves defending against attack scenarios (Black Hills, nd). Cards include four categories of Attacks (Initial Compromise, Pivot and Escalate, C2 and Exfil, and Persistence), plus Procedures and Injects. An attack scenario is created by a player designated as 'Incident Captain', and one or more further players then take the role of Defenders (drawing from Procedure cards to counter the attack). Games typically last 30-60 minutes, and end if the Defenders have successfully revealed all four attacks, or if ten turns have been taken.
- **Control-Alt-Hack**: A card-based game based on the scenario of players working for a white-hat ethical hacking company (Denning et al, 2013). The game is based around Hackers with different skills (e.g. cryptanalysis, hardware hacking, social engineering) being required to complete Missions (which involve a number of required tasks). Play involves rolling numbered dice to determine what level of skill is required for each task in the Mission, and then seeing if the player's Hacker has that level. Entropy cards, Money and Hacker Cred tokens are also involved in the gameplay, and games last around one hour.
- **Cyber Threat Defender**: A two-player game involving four types of cards - Assets, Defences, Events and Attacks (CIAS, 2024). Players create a network of Assets, and build Defences to protect them from Attacks. Events then occur that may help or harm security. Each card has a resulting effect, and a points value. Games take an average of 20 minutes, and end when a player wins (by reaching 30 points) or loses (by reaching -45).
- **Decisions & Disruptions**: A LEGO-based tabletop game, focused around industrial control systems security, in which 5-8 players are responsible for managing the security of a small utility company (Frey et al, 2019). The LEGO pieces are used to construct the environment and defences, and players then make decisions about how to protect against attacks, while working within the limits of their budget. A Game Master is needed to run the game and play lasts up to two hours.
- **Riskio**: A tabletop game in which players protect their organisation's data and services against various threats (with 78 related cards covering categories of Spoofing, Tampering, Repudiation, Information Disclosure, Denial of services, and Elevation of Privilege) (Hart et al, 2020). Games need 3-5 players, plus an experienced cyber professional to act as Games Master, and can last around 45 minutes

Even this small sample highlights that while a range of games are available, most are clearly designed for relatively long-form play and are often focus on aspects of cybersecurity that go beyond the interest of a layperson audience. As such, while very valid in their target space, they do not lend themselves to more casual use or towards promoting more entry-level cybersecurity concepts. This is not meant to be seen as a criticism of the existing games. All are fit for their intended purpose, but it is important to be clear on what that purpose is. For example, they are all very suitable as educational aids for those already active or interested in cybersecurity (e.g. for cybersecurity students, cyber teams within organisations etc), but arguably less suited to a more general population. Indeed, none appear to have been designed for promoting initial engagement and awareness raising, and so there is an opportunity for games and related activities that fit within this space.

3. Expanding the Landscape of Games for Cyber Security Engagement and Awareness

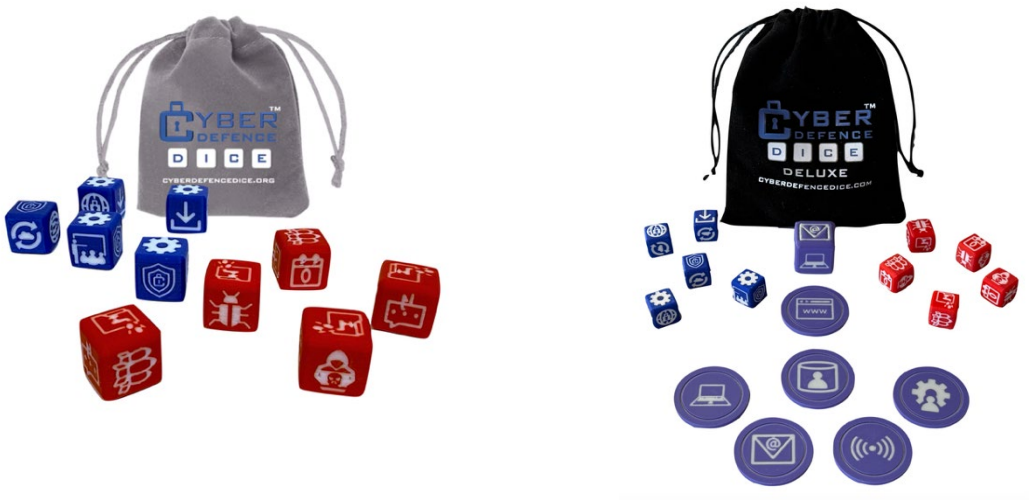
Having identified the gap offered by the existing games, the authors have created a series of gamified physical cyber-engagement activities:

- *Cyber Defence Dice* – an awareness raising game of attack and defence
- *Hacker Whacker* – a fast-paced arcade style game that raises awareness of assets, threats and safeguards
- *Password Enlightener* – a password meter realised in the manner of a light-up fairground-style strength tester machine.

These have collectively been designed for use in public-facing events and offer a means of attracting interest amongst both general audiences and more specific groups, such as young people and small business owners.

The Cyber Defence Dice and Hacker Whacker games are both based around a common set of cybersecurity concepts, in terms of Assets (i.e. elements that require protection), Threats (i.e. events that could harm the Assets), and Defences (i.e. cybersecurity safeguards that protect against the Threats). These are illustrated in Table 1, along with the images that we have designed to represent each of them. In terms of incorporating them into the gameplay, Hacker Whacker promotes basic recognition of the different items, whereas Cyber Defence Dice introduces interrelationships between them and elements of decision making. The images were specifically designed to ensure that they would be able to be rendered clearly when 3D printing a standard six-sided die.

Table 1: Assets, Threats and Safeguards used in the games



Assets	Threats	Defences
 Admin Account	 Malware	 System and App Updates
 Email Server	 Hackers	 User Awareness
 Personal Computer	 Accidental Breach	 Backup
 Personal Data	 Phishing	 Secure Configuration
 Website	 Denial of Service	 Internet Security
 Wireless Router	 Zero Day Attack	 Defence in Depth

3.1 Cyber Defence Dice

Cyber Defence Dice offers an entirely physical engagement experience, based upon the concepts of attack and defence. The basic premise of the game involves one side (which can be an individual player or a small team of up to 4-5 people) playing the role of an attacker and the other side taking the role of defender. Attacks and defences are mounted by means of dice rolls, with each side having an associated set of five dice. The attacker dice are red (reflecting the notion of a Red Team in cybersecurity testing), with the six die faces reflecting the Threats from Figure 1. Meanwhile, the defender dice are Blue (again, reflecting the established cybersecurity concept of a Blue Team being defenders), with the die faces taken from the Defences in Figure 1. The game works by attackers throwing a suitable set of threats, and defenders then throwing their dice in an attempt to offer a suitable defence (alternatively, the defenders can start, with the attackers then trying to beat the security posture that has been established). The starting side can take up to three throws and can keep or re-roll whatever dice they choose on their second or third attempts. They may, however, elect to stop after one or two rolls, and the other side is then also limited to that number of rolls when making their response. Players use an accompanying reference card to confirm which attacks beat which defences and vice versa.

The core version of the game is called Match Mode, where players must meet (to draw) or exceed (to win) the *number* of matching dice thrown by the other side, using a defence (or attack) *type* that is matched to the attack (or defence) *type* previously thrown. The authors have also created rules for two alternative game variants (called Combinations, and Attack Matcher), as well as an extension to Match Mode that makes use of Assets, While the presentation of the full game rules is outside the scope of this paper, interested readers can refer to www.cyberdefencedice.com for more details (which includes descriptions of different game variants and worked examples of gameplay). Additionally, the background to the core game, and details of associated evaluations are reported in Furnell et al. (2026).

The game is produced in standard and deluxe versions, as depicted in Figure 1, with the difference being that the latter incorporates the use of assets that players must compete to acquire or protect. These are represented by tokens, with each asset type being targeted via different combinations of attack or defence (with players again being able to use the accompanying reference card to check which attacks/defences work for which assets).

(a) (b)

Figure 1: Cyber Defence Dice in (a) standard and (b) deluxe formats

The dice and asset tokens are 3D printed in-house, with the accompanying imagery also having been designed and drawn by the authors. Additionally, sets of larger format dice have also been produced for use in public engagement events such as exhibitions. These are designed to be thrown on the floor, as shown in Figure 2.

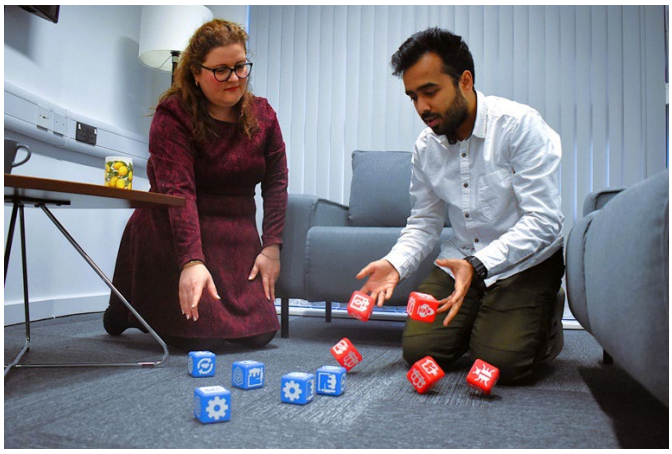


Figure 2: Playing with large format dice

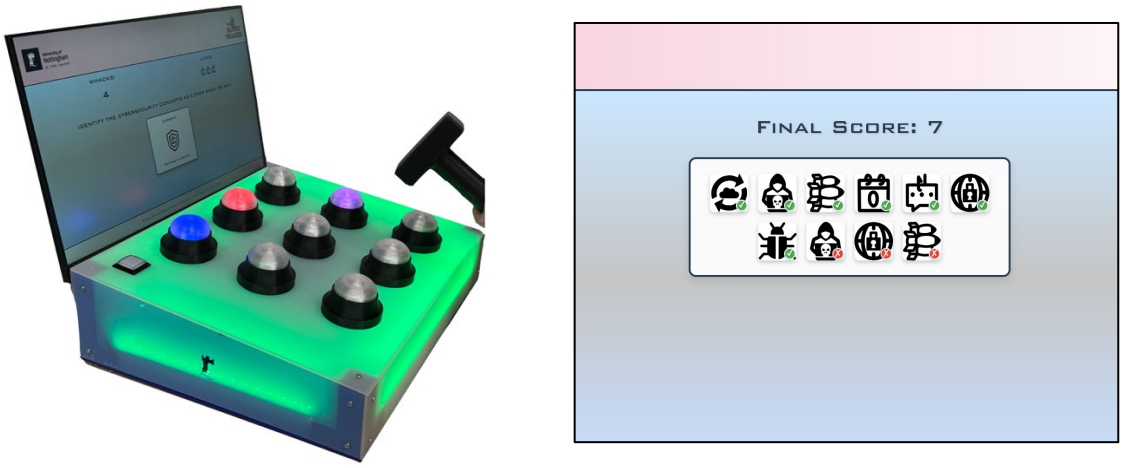
The game has been successfully play-tested with a range of audiences (including groups from the general public, as well as those already familiar with the concepts, such as cybersecurity students and professionals), with positive ratings being obtained in relation to both the awareness value and the enjoyability of the game. It has also been used as a basis for teaching and awareness-raising sessions for small businesses.



3.2 Hacker Whacker

Inspired by the popular arcade game Whac-a-Mole, Hacker Whacker is a custom device, designed and implemented by the authors (Todd et al. 2026). The game uses the same images as the Cyber Defence Dice, but this time they appear on-screen and players are required to recognise and respond to the category being shown. Unlike the colour-coded usage in the dice game, the images now appear as simple black on white representations so as not to convey which category they belong to. The game has two variants:

- *Threats and Safeguards* – Blue and red buttons illuminate on the playboard, with players needing to hit the blue button if the current image is a safeguard, or the red button if it is a threat.
- *Assets, Threats and Safeguards* – As above, but with displayed images also including the Assets, and a purple button also being lit on the playboard (i.e. the player now needs to correctly hit one of three displayed colours).

In both cases, the players must react quickly enough (i.e. before the image changes and the light pattern changes) and hit the appropriate button to match the category of the item shown on screen. If they fail to do so

within a time limit (which starts at a couple of seconds and reduces as the game progresses), or they hit the wrong button, then they lose a life. The game ends after three lives are lost, at which point the player is shown a summary of all the items they were presented with, and whether they got each one right or wrong. Figure 3 shows the game in action, with the Threats and Safeguards variant being played, as well as the feedback delivered to the player at the end of the game.

(a) (b)

Figure 3: The Hacker Whacker game (a) device, and (b) example end-of-game summary

It is to be expected that many players initially score poorly because they may not *recognise* the threats, safeguards and assets, and so part of the learning value of the gameplay is that it enables these concepts to be reinforced as they play further. At the same time, the learning potential of the game is ultimately limited, as there is no basis for players to go *beyond* this once the initial lessons have been learned. As such, repeated gameplay simply serves to reinforce notions of things that are good or bad, and does not have any of the resulting decision-making aspects that occur in Cyber Defence Dice. Having said this, the time investment in the game - even if somebody plays multiple times - is only a few minutes, and so the awareness-raising outcome still represents a reasonable return on investment relative to the time involved. Moreover, the arcade-style nature of the game has the potential to attract players that may not be interested in playing dice, and so opens the opportunity for resulting engagement in a different way.

3.3 Password Enlightener

The issue of user authentication is one that is notably missing from the defences represented in the other games, but it is specifically the focus of the Password Enlightener device. This, as shown in Figure 4, is a password meter reimagined in the form of a fairground style 'test your strength' machine. The concept of password meters will already be familiar to many through their use of websites (de Carné de Carnavalet and Mannan, 2014), and so the Enlightener typically requires little explanation for first time users. The device is more of an engagement activity than a game, but participants do tend to end up competing with each other to achieve better scores.

The player enters their password via the touchscreen at the bottom of the device (Figure 4b), and then presses the large illuminated red button to initiate the assessment. The scoring process is then based on a series of checks:

- assessing the length and complexity of the string
- checking against a dictionary of commonly leaked passwords
- calculating how long it would take to brute force the string
- checking if character substitution has been used (e.g. h3ll0, Croiss@nt) using a reverse leet algorithm (to identify use of common words with substituted characters)
- looking for patterns (e.g. dates, repetitive words etc.)

In addition to the rating, which is revealed by the progressive lighting of the lights, the player is also provided with some resulting feedback (Figure 4c) that explains the implications of their score and how it was determined.

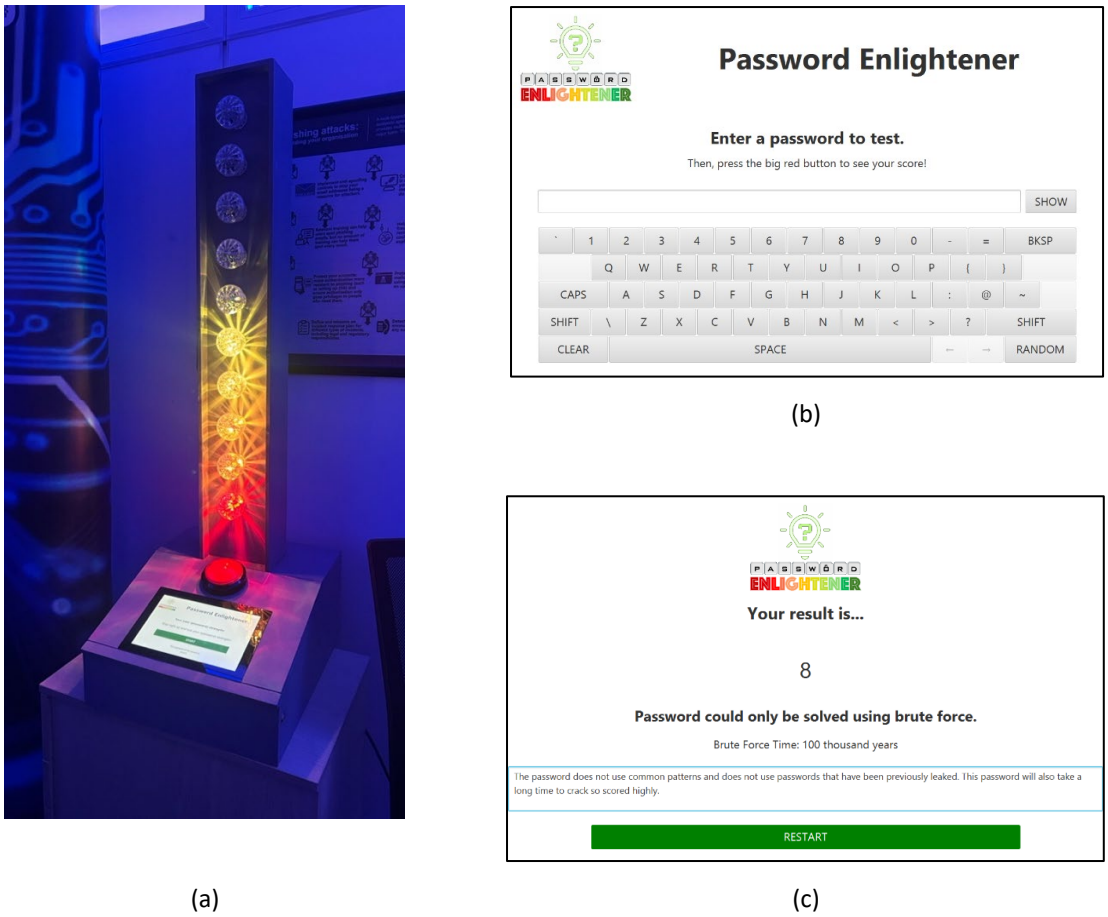


Figure 4: The Password Enlightener (a) device, (b) password entry and (c) example of feedback

This game is typically the one case in which players come to the activity with some pre-existing knowledge around what is involved. Many already have (and often express) some level of expectation around how their password will score ("I think mine is really bad", "I use a very strong password" etc). The main concern from the more security-aware users is "Are you capturing the passwords?", and this is not the aim of the exercise. Regardless of whether the question arises, players are assured that their passwords are not stored in any way and that no further use is made of them. Users are also advised to be cautious if they plan to enter an existing password in case somebody is observing (given that shoulder surfing or filming of their activity cannot be ruled out in public events).

In most events the device has been made available for visitors to come and use on an individual basis. However, it is also possible to use it in a more structured manner, with a group of players being asked to create new passwords and take turns to enter them on the device to see who scores the best. To ensure fair play, and show that they can remember the information rather than just type something in that maximises their score, the process works as follows:

- Each player writes their candidate password on a piece of paper, and then turns their paper over.
- Players take turns to enter their passwords and record the scores. On each attempt, the person running the Password Enlightener reveals the password on the device and makes a note of it.
- When all players have taken their turn, everyone then writes their password again, on the blank side of their paper.
- The team member can then check that the winning player(s) have written the *same* password on both sides of their paper (i.e. that they could remember it for the duration of the activity) and that this also matches what was entered on the device (i.e. that they did not cheat by remembering something easy and then entering a more lengthy or complex string on the device in order to score better).

The learning outcome tends to be a level of reassurance if indeed the players prove themselves able to select and enter strong passwords, or alternatively a pause for thought if they enter a password that scores poorly. In the latter case team members running the activity can give advice on strategies for improving password strength

(e.g. focusing on the length and using techniques such as three random words (McCormack, 2016) to aid memorability). The memorability of what was entered is a key issue, and many players readily discover that they can score highly by entering long strings of random characters. However, they soon fall foul this if the team member running the activity asked them to enter the same thing again, in some cases introducing an additional lesson about the memorability of passwords.

4. Discussion

When considering them as provocations of interest, the games clearly have potential to attract players for different reasons. The dice offer a direct basis for players to compete against each other, while Hacker Whackers delivers a fast-paced arcade experience. Meanwhile, Password Enlightener works on the basis of potential curiosity about how well they may be able to score. In all cases, the visual prompts (the colours of the dice, the coloured lights of the devices) and the kinetic activities (throwing the dice, hitting the buttons) provide further elements that help to generate interest and draw people in.

As previously mentioned, each of the games has proven successful in the context of public engagement events, and Figure 5 shows an example of the three activities ready for use in such a setting. The extent of engagement in this context can still vary. Some players will come, have a go, and then leave. Others will stay for longer and have multiple attempts (sometimes then needing to be encouraged to let someone else have a go). In all cases, their engagement offers an opening to discuss the cybersecurity concepts involved, whether they understand the threats, protect their own systems, and so on. As such, even in an event context there is the opportunity for some basic awareness raising to occur. However, this can be enhanced further if the activities are used in more structured settings, such as being a prelude or accompaniment to a more specific security awareness session.

Figure 5: An example of activity setup for an engagement event

When comparing the new games to those discussed earlier, the other tabletop games are all more substantial in terms of their game dynamics and complexity. However, there is also a trade-off to be recognised. The other games may provide more depth in terms of the cybersecurity learning experience, but equally they require a much more significant investment of time to both understand and play the games. This in turn potentially reduces the audience to those with the time and inclination to take part. An interesting basis for illustrating this is to compare the instructions/guides that accompany each of the games, the length and readability of which is likely to further influence their accessibility and applicability to different audiences. For example, if there is a lot to read and/or the language is complex, then this could represent a barrier to some players. To this end, the instructions for the five games listed earlier in the paper were assessed, alongside those from Cyber Defence Dice (listing the standard and 'Deluxe' versions of the game separately, as the latter requires additional text to be read to understand the use of Assets). The 'Editor' feature within Microsoft Word was used to perform the assessments, and in each case the input in was raw text describing the game and how to play it (with documents having been stripped of title pages, table of contents, tables, appendices, etc). Hacker Whacker and the Password Enlightener were excluded because they have no accompanying instruction booklets – brief guidance is displayed on-screen and the rules can quickly be determined from play and observation. While not quite as brief as the classic instructions that appeared on Atari's Pong machine (i.e. "Ball will serve automatically. Avoid missing ball for high score"), players have proven to require little guidance to get going.

The findings are shown in Table 2 and there is some clear variation in the amount of text that the players need to read to understand and play the games. While several amount to the equivalent of just a couple of pages of text, others are considerably lengthier. In addition to this, it is also relevant to consider the ease with which potential players may understand what they are reading. The Flesch Reading Ease score assesses the average sentence length (words per sentence) and the average number of syllables per word. It delivers a resulting score between 0 and 100, with a higher score denoting text that is easier to read (Flesch, 1948). From the table, we can see that four of the entries in fall into the 70-80 range (which is classed as 'Fairly easy to read'), while two are in the 60-70 band (which is considered to be 'Plain English', and easily understood by those in their early teens). The outlier in the table, in both length and readability is Decisions and Disruptions, where the Reading Ease score that falls into the 'Difficult to read' category (30-50). This is also reflected in the higher Grade Level score, which indicates the US school grade at which someone would be expected to be able to read and understand the text.

Table 2: Comparing the length and readability of instructions for different games

Game	Source Material	Words	Flesch Reading Ease	Flesch-Kincaid Grade Level

Riskio	www.riskio.co.uk/game-play-setup www.riskio.co.uk/game-play-attack www.riskio.co.uk/game-play-attack-1 www.riskio.co.uk/game-play-information-deck	941	62.1	9

When interpreting the results for the Cyber Defence Dice, it should be noted that the full guide covers different game variants and includes other supporting information. As such, the assessments in the table are based specifically upon the text that needs to be read to understand and play the main version of the game. This includes the general rules, the specific rules for the core game (Match Mode), and the descriptive text for a worked example (which is also accompanied by illustrations in the guide itself). It excludes background information about the threats and defence types, descriptions of alternative game modes, and a section that discusses parallels to real-world cybersecurity. All of these would, of course add to the word count and affect other scores, but they do not *need* to be read to understand and play the core game. Moreover, the essence of the standard game can be distilled down to a much more succinct set of rules, as presented in the Quick Reference Guide provided in the dice pouch. These are expressed as follows, in 60 words (with the Reading Ease reaching 83.2 and the Grade Level now just 4.9):

> *"Either side may start and has up to 3 throws, but can stop after 1 or 2 if preferred. The responding side is limited to that number of throws. Players choose which dice to keep or throw again. To win a round, throw more defence dice than the corresponding attack (or vice versa). A matching number is considered a draw."*

They are accompanied on the reference card (see Figure 6) by a list of the Threats and Defences (presenting the images alongside the names), plus the two matrices (showing which attacks beat which defences, and vice

versa). If players are comfortable with the outline and how the matrices work, then they may not need the more descriptive guidance and the worked example from the full rules.

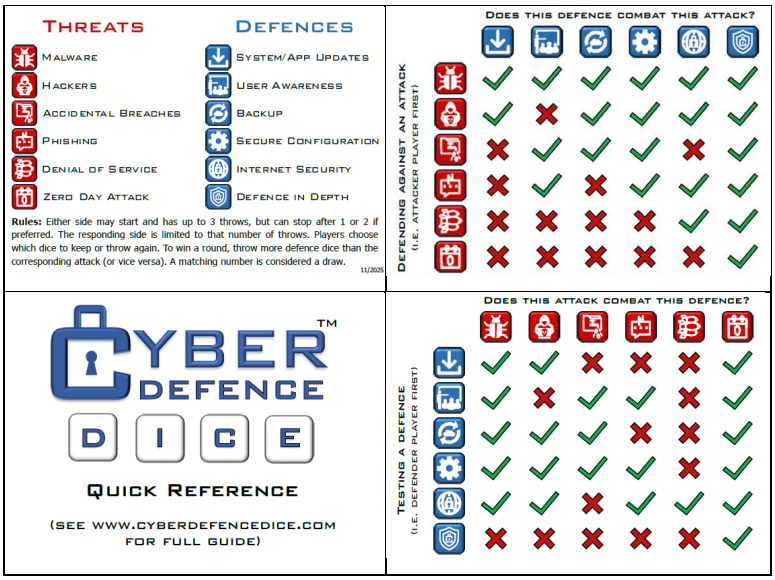

Figure 6: Cyber Defence Dice Reference Card

Another aspect to note is that the above is just considering the presentation of the text required to explain the game – it does not start to address whether they understand the *concepts* under discussion. While the Cyber Defence Dice instructions briefly explain the nature of the Threats, Defences and Assets, the other game guides rarely do this - the player is assumed to know about the basic cybersecurity issues involved, or (where appropriate) to be able to get guidance from the Game Master. For example, while Backdoors and Breaches has a relatively low word count and good readability scores, what it is actually referring to includes some potentially challenging security concepts. For example, even the names of the attack categories highlighted earlier (e.g. Pivot and Escalate, C2 and Exfil) – are unlikely to be immediately meaningful to a lay audience. Picking some examples of terminology from the card titles (e.g. Dynamic Link Library Hijacking, Domain Fronting as C2, External Password Spray, and Kerberoasting) makes it very clear that players are expected to have some significant prior knowledge in the domain.

The lower barriers to entry are not intended to imply that the Cyber Defence Dice is 'better' than the other games, but it does help to further illustrate that it is simpler. Whether this is a good or bad thing depends upon how it is intended to be used. Part of the reason that some of the game guides are more substantial is because there is more to learn. The games themselves go deeper into cybersecurity concepts and decision making (thereby addressing different audiences), and so there is a clear trade-off (or indeed trade-up) to be made against the effort required to learn how to play them. However, if the aim is to have a means of capturing initial interest and engagement, then the dice (and Hacker Whacker and Password Enlightener) are likely to offer the more suitable basis for doing so.

5. Conclusions

As in other disciplines, gamification offers a means of making cybersecurity more accessible and interesting for those who might otherwise find it less engaging. At the same time, the nature of the game needs to be matched to the target audience involved. Those with limited cybersecurity knowledge and awareness are clearly a desirable population to assist, but many of the existing games are aimed above this level. In contrast, the three games presented in this paper offer contributions more directly suited to a layperson audience. While the nature of the underlying games is very different, they share the characteristic of being quick and providing a foundation for further engagement.

All three games have been designed in ways which maximise their ability to provoke interest at events. Both Hacker Whacker and the Password Enlightener have been used at many such events, and have proven to attract players through their lights, sounds, hammer (Hacker Whacker) and large red button (Password Enlightener). Cyber Defence Dice has also been used at various events, with the larger format dice proving successful at attracting attention due to their physical size and novelty, and the smaller sets being popular giveaways, allowing

attendees to continue their education after the event. Further developments are intended, including inclusion of extra features to the game play of Hacker Whacker and the Password Enlightener, whilst still maintaining the prompt playtime and interactivity levels that have currently been achieved.

Ethics and AI declarations: The playtesting of the Cyber Defence Dice was approved by the School of Computer Science Research Ethics Committee at the University of Nottingham (CS-2024-R44). All participants read and signed associated consent forms before play began. AI tools were not used in the writing of this paper.

Abstract: Encryption keys require careful management, they must be securely stored, and if stolen or compromised, the consequences can be catastrophic. Ephemeral keys are created, used and then deleted, reducing the attack surface. As the tactics, techniques and procedures of threat actors continue to evolve, implementing an ephemeral encryption key would enhance the protection of critical infrastructure systems, sensitive data and communication systems. This research investigates the feasibility of generating a repeatable, unique, yet transient encryption key from human biomarkers. By deriving cryptographic keys directly from bioelectrical and biochemical markers, key management overhead and long-term exposure risks can be minimized. This Systematization of Knowledge (SoK) addresses two primary challenges. Firstly, determining the viability and limitations of deriving consistent keys from inherently variable biomarkers. Secondly, we propose a manifold encryption key derivation scheme using context dependent signals drawn from the network, device and environment to overcome the limitations of biometric based key generation, including irrevocability, noise, and entropy deficiency.

Keywords: Biomarker, Cryptography, Data security, Encryption keys

1. Introduction

Cryptography, commonly referred to as encryption, constitutes the systematic process of transforming information into a secure form such that its content remains unintelligible to unauthorized parties. With the continual escalation of cybercrime, the development of increasingly robust encryption methods is imperative to mitigate potential security breaches (Diffie et al, 1976; Rivest et al, 1978; Lutsenko et al, 2021). According to IBM, the global average cost of a data breach as of 2025 is USD 4.44 million, as shown in Figure 1 (Kessem, 2025).

Given the pervasive integration of digital technologies, encryption underpins a wide array of everyday activity, including financial transactions, authentication protocols, electronic commerce, numerous communication apps, and social networking platforms (Ozer et al, 2024; Marappan et al, 2025; Qiu et al, 2020; Talwar et al, 2022). The protection of such data is typically achieved through the application of cryptographic algorithms designed to ensure confidentiality and integrity.

Traditional authentication schemes rely on tokens or secret knowledge to establish identity but cannot distinguish a legitimate user from an adversary who has obtained those credentials (Uludag et al., 2004; Sheng et al., 2012). Biometric authentication addresses this by leveraging unique physiological and behavioural characteristics, including fingerprints, face, iris, or voice, that are inherently tied to the individual rather than to a possession or secret (Pahuja et al., 2024; Alrawili et al., 2024). In practice, systems operate in two phases: enrolment, where biometric data is captured and stored as a reference template, and verification, where subsequent inputs are matched against that template within a defined threshold. Systems may be unimodal or multimodal, the latter combining multiple traits to improve accuracy and robustness (Pahuja et al., 2024; Sheng et al., 2012). Despite these advantages, biometric systems remain vulnerable to template theft, presentation and replay attacks, side-channel exploits, and insider misuse, while system accuracy is further sensitive to factors such as age, illness, injury, illumination, and noise (Alrawili et al., 2024).

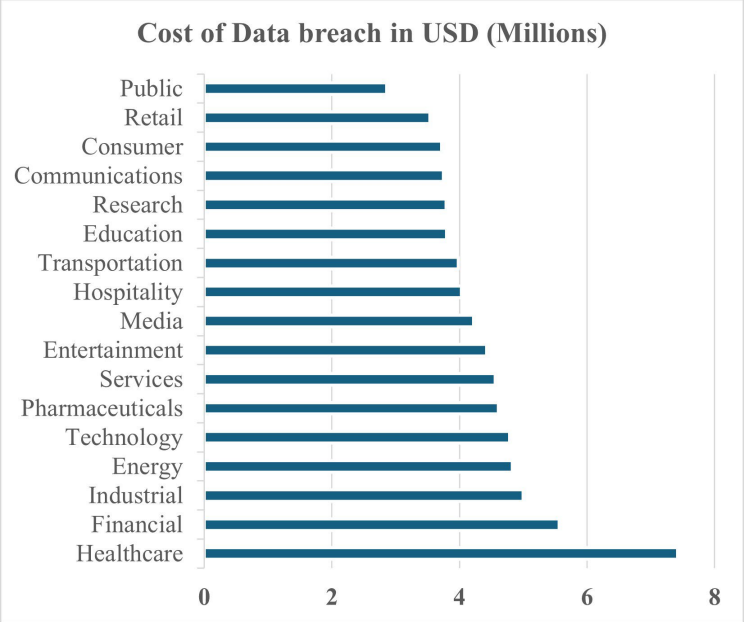

Figure 1: Cost of data breaches as of 2025 by IBM (Kessem et al)

Biometric authentication, as described above, ultimately reduces to a binary decision: a score is computed, compared against a threshold, and access is granted or denied. While effective for identity verification, this model does not generate cryptographic material, the biometric serves as a gate, not a key. The shift from authentication to cryptographic key generation is non-trivial. Where authentication tolerates variability through a soft threshold, key generation demands exact or near-exact reproducibility of a fixed bitstring across presentations. An active area of research pursues a more fundamental integration, where biometric traits are used to generate or protect encryption keys that underpin critical security services including confidential communication, ensuring the integrity of data, and enabling non-repudiation through digital signatures (Lutsenko et al, 2021; Cowley et al, 2025; Gorski and Wodo, 2024). The potential of this integration lies in producing cryptographic material that is user specific and challenging to replicate. Biometric key generation offers a major advantage, it removes the need to store or remember external keys or passwords as the key can be reconstructed as required (Lutsenko et al, 2021; Sheng et al, 2012). However, current frameworks often lack formal security proofs, rigorous entropy analysis, and practical mechanisms for error tolerance or revocability, leaving their robustness uncertain (Sheng et al, 2012; Uludag et al, 2004). These limitations motivate the need for a systematic study of biometric key generation approaches and the exploration of new frameworks that integrate biometrics with complementary signals for stronger, more adaptable cryptographic systems.

1.1 Key Contributions

Our main contributions are summarized as follows:

- We develop a comprehensive Systematization of Knowledge (SoK) on biometric based encryption key generation.
- We provide a structured critique of prior approaches, highlighting open challenges in entropy estimation, error tolerance, revocability, and compliance with Kerckhoffs's principle.
- We propose a novel manifold key generation framework that binds biometric traits with complementary context dependent signals from network, environmental, and device hardware markers to enhance resilience against attacks.

To the best of our knowledge, the use of environmental, hardware, and network markers in conjunction with biometric features for encryption key generation has not been previously examined, positioning this work as a foundation for future experimental validation and benchmarking.

2. Fundamentals and Background

Biometric cryptosystems are typically categorised into three main categories: Key Release, Key Binding, and Key Generation as shown in Figure 2.

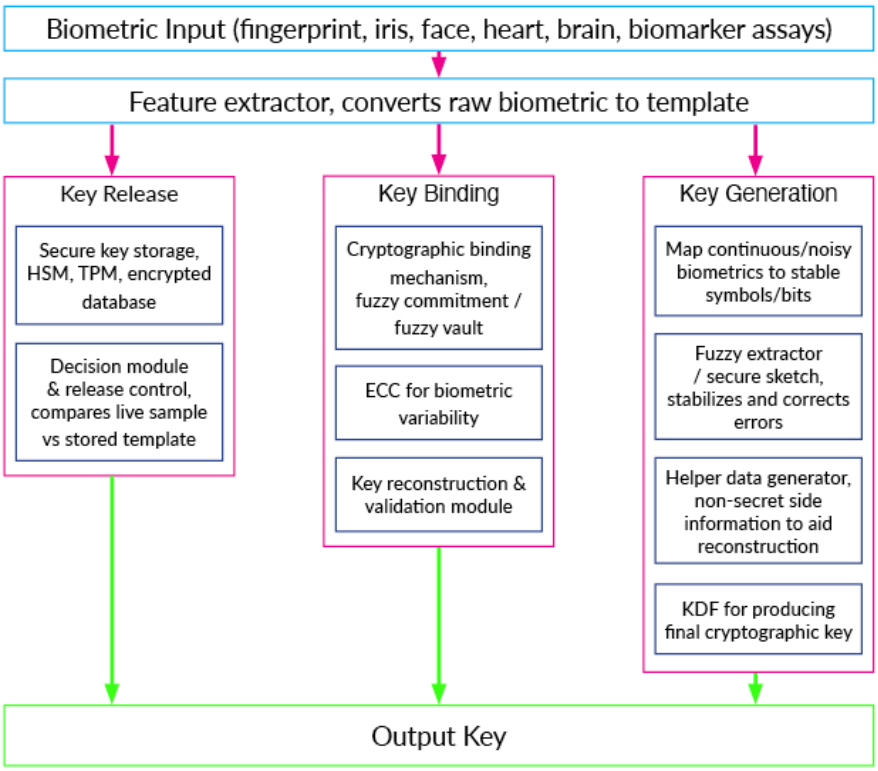

Figure 2: Biometric Encryption Key Systems

In Key Release systems, a conventional cryptographic key is stored securely, in a Hardware Security Module (HSM) or Trusted Platform Module (TPM) and only released after a successful biometric authentication (Lutsenko et al, 2021). Key Bindings systems mathematically bind a cryptographic key with biometric data using various error tolerant algorithms, where the key cannot be retrieved without the biometric data. This approach depends heavily on Error Correction Codes (ECC) for biometric variability (Lutsenko et al, 2021). In Key Generation systems, the key is directly generated from biometric features using a Key Derivation Function (KDF), that variously use fuzzy extractors and helper data (Lutsenko et al, 2021). Key generation systems regenerate cryptographic keys directly from biometric data, eliminating the need to store keys, but at the cost of easy revocation or rotation. To avoid ambiguity, we clarify the terminology used throughout this work.

2.1 Helper Data

A string, data, or a system that is extra information produced at enrolment to enable reliable reconstruction of a secret from a noisy source such as biometrics (Gebali et al, 2022). However, many works deviate, treating helper data as confidential or hardware-protected, or omitting it entirely in favour of direct mappings, trusted hardware, or a user secret such as a PIN. In this paper, we use *helper data* to mean any auxiliary string intended to aid reproducibility.

2.2 Secure Sketch

A primitive with two algorithms: Sketch(w) → s and Rec(w′, s) → w, where w is the enrolment biometric, w′ is the verification sample, and s is the helper data, with w and w′ within a threshold under a chosen distance metric. Correctness: if w′ is within that threshold of w, Rec recovers w with high probability. Security: s reveals only bounded information about w and typically preserves most of w's minimum entropy (Dodis et al, 2008). A secure sketch enables reproducibility from noisy inputs but does not itself ensure that the final key is uniformly random.

2.3 Information Reconciliation

This follows the classical noisy-channel key agreement paradigm, where information reconciliation uses ECC to resolve correlated but noisy values into an identical string, with the side-channel communication serving as helper data (Gorski and Wodo, 2024).

2.4 Fuzzy Extractor

A fuzzy extractor is a pair of algorithms Generate and Reproduce that derive a stable cryptographic key from a noisy biometric measurement. A fuzzy extractor can be viewed as a *secure sketch* for reproducibility plus privacy amplification for uniformity (Dodis et al, 2008). Generation: *(R, P)* ← Gen*(w),* where *R* is the secret key and *P* is public helper data that may be stored or transmitted. Reconstruction: Given any fresh sample *w′* that is sufficiently *close* to *w* under a chosen metric, the algorithm Rep reproduces the same key: Rep(*w′, P*) = R. Correctness: If *w′* is within the tolerated noise radius of *w*, reconstruction succeeds with high probability. Security: For any source *W* with sufficient minimum entropy, the key *R* is *nearly* indistinguishable from a uniform ℓ bit string and independent of *P*.

2.5 Security Analysis

In a biometric key generation system, security can be assessed across four principal layers: the Sensor Layer, the Preprocessing Layer, the Feature Extraction Layer, and the Key Derivation Layer, each introducing unique attack vectors and corresponding defences, as shown in Figure 3.

At the sensor layer, where raw biometric signals are captured, attacks include presentation spoofing, replay injection, and environmental manipulation. Defences include Presentation Attack Detection (PAD), multi-spectral or 3D sensing, cryptographically authenticated sensor links to prevent MITM attacks, and hardware attestation to protect sensor firmware.

The preprocessing layer, which cleans and normalizes raw data, may be targeted through adversarial perturbations, calibration tampering, or parameter rollback. Defences include robust normalization, cryptographic integrity protection of configuration parameters, and execution within a Trusted Execution Environment (TEE).

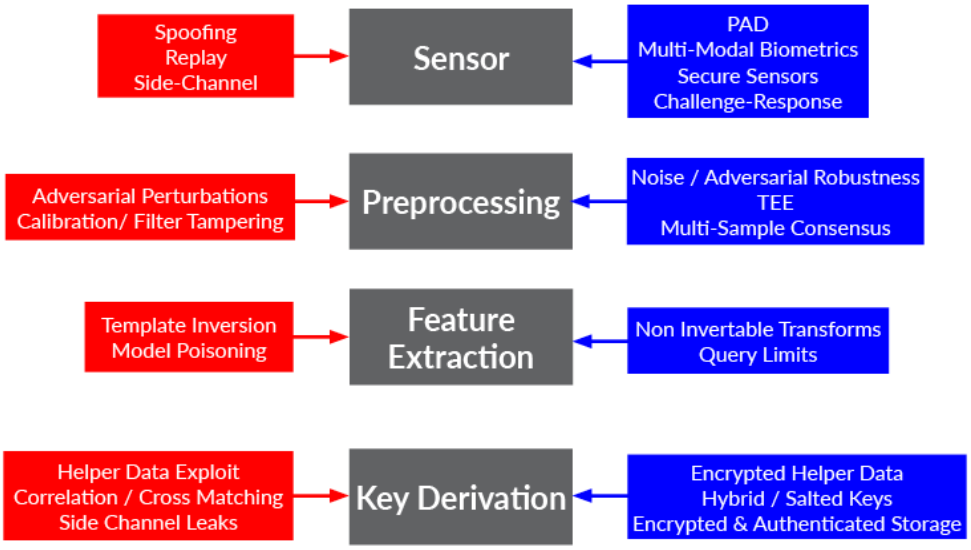

Figure 3: Biometric Key Generation showing potential attack vectors and defences at each stage

At the feature extraction layer, threats include template inversion and hill-climbing attacks exploiting repeated queries. Defences focus on non-invertible feature transforms, restricted query access, and hardening models against poisoning.

The key derivation layer converts noisy biometric features into reproducible cryptographic keys via feature quantization, error correction using secure sketches or fuzzy extractors, and a KDF to produce the final key.

3. Analysing the State-of-the-Art

This section surveys recent biometric key derivation schemes, with Table 1 providing a structured comparison. The analysis follows the framework established in Section 2 and evaluates each work along two axes. First, which of the four key-generation building blocks, namely helper data, secure sketches, information reconciliation, and fuzzy extractors, are instantiated, how explicitly, and whether their security properties are formally or empirically justified. Second, security coverage across the sensor, pre-processing, feature

extraction, and key derivation layers, with attention to presentation attacks, replay, template inversion, and offline guessing.

A key evaluative criterion throughout is Kerckhoffs's Principle, that system security must rest solely on the secrecy of the key, not on obscured parameters, undisclosed feature selection, or protected helper data (Petitcolas, 2025). Section 3.5 synthesises the resulting research gaps.

3.1 Reproducibility Versus Leakage in Helper Data and Kerckhoffs Compliance

A persistent tension across the literature is that reliable key reconstruction from noisy biometrics requires auxiliary information, yet auxiliary information risks leakage and is often handled in ways that undermine Kerckhoffs compliance. Cowley et al. (2025) sidestep the problem entirely by mapping immunoassay absorbance values directly into an AES-compatible string with no secure sketch, reconciliation, or fuzzy extraction. This avoids helper-data leakage but shifts the burden onto experimental repeatability and parameter secrecy, making key reproduction fragile and Kerckhoffs compliance weak. Ballard et al. (2008) take a different approach, explicitly addressing the problem that biometrics alone can be too predictable or too noisy for key generation. Their Randomized Biometric Templates (RBTs), evaluated on handwriting, add entropy by introducing uncertainty in the measurement process rather than relying solely on biometric randomness. A key design objective is that decrypting a stored template under an incorrect password still yields a plausible output, preventing offline password-checking and obscuring which features are in use. This is a more cryptographically deliberate handling of auxiliary information than in many applied schemes. However, no information-theoretic leakage bound is provided, the construction sits outside the fuzzy extractor paradigm rather than instantiating it, and a non-trivial minority of users remain susceptible to rapid key recovery by search.

Rathgeb and Uhl (2011) follow the classical public helper-data model, storing a bit mask of stable iris code positions alongside cyclic error-correcting redundancy, which allows a fresh noisy sample to be decoded back to the original representation, to enable repeatable reconstruction. The design moves closer to a reproducible-key pipeline, but residual entropy is not tightly bounded, and the security analysis rests on iris code bit independence assumptions known to be imperfect. Kuznetsov et al. (2024) similarly publish a helper string in a code based pipeline without fully accounting for what it reveals about residual entropy under realistic feature distributions. Across these works, helper data is either omitted, which weakens reproducibility, or introduced without complete leakage accounting, sometimes with implicit secrecy assumptions filling the gap. This

pattern highlights the need to consider whether helper data is public, what it leaks, and how it can be revoked as fundamental design requirements rather than implementation details.

3.2 Error Tolerance and Effective Entropy Under Noise Correction

The relationship between noise tolerance and effective key strength presents its own complications. Many papers report AES-length outputs, but key length is not a security guarantee when the mapping from biometrics to bits is biased, redundant, or requires substantial correction. In schemes that attempt deterministic reconstruction, error correction and redundancy unavoidably trade off against entropy. That is, selecting stable bits, partitioning continuous features into tolerance bands, and publishing ECC redundancy can all reduce the attacker's search space, especially if bit distributions are non-uniform or correlated.

Rathgeb and Uhl (2011) make this trade off explicit by using ECC to correct bit flips in selected iris-code positions. Kuznetsov et al. (2024) likewise analyse FRR/FAR trade-offs under code parameters in a code-based fuzzy extractor setting. These schemes are stronger than direct mappings because they use a correction mechanism, but their security interpretation still hinges on how much uncertainty remains after feature selection and redundancy publication. In contrast, Cowley et al. (2025) highlight a different failure mode, an AES compatible string can be produced without explicit correction, yet small measurement deviations can render reconstruction infeasible, and the usable uncertainty can be far below the nominal key size. Szymoniak et al. (2025) illustrate a related risk of overstating key strength. Their IoT oriented scheme derives a nominal 256-bit key from a facial triangle using the eye corners and chin. However, the effective uncertainty is constrained by the low-dimensional geometry of the underlying biometric signal and by acquisition conditions including pose, lighting, expression, that alter coordinates without any ECC or secure-sketch mechanism to stabilise them. Consequently, the reported key length primarily reflects output formatting rather than a quantified entropy guarantee.

A related strategy appears in several Machine Learning (ML) based bio-key papers where rather than enforcing deterministic reconstruction, they relax the success condition to similarity under a threshold. This improves apparent robustness with lower rejection but transforms the problem into verification rather than cryptographic key generation, as the output is not guaranteed to be identical across sessions. The literature repeatedly confronts the same issue where the robust handling of noise is essential, but it must be evaluated together with the entropy cost of tolerance mechanisms and the gap between output length and effective security.

3.3 Distinguishing Biometric Verification from Cryptographic key Generation

A substantial portion of recent work, particularly ML systems, implicitly adopts a verification paradigm even when describing outputs as keys. In these designs, bitstrings produced from different sessions are not required to match exactly; instead, authentication is decided by Hamming distance or related similarity scores, against an optimised threshold. This is legitimate and often effective for authentication, but it does not directly produce encryption ready keys because encryption requires absolute key agreement.

Kocak et al. (2025) use this pattern using ECG heart prints. Their Siamese neural network produces 256-bit outputs designed to be consistent within user and different across users, and ECG is argued to be intrinsically harder to spoof than external traits. However, the system is evaluated as a matcher. Keys are close rather than identical, and no reconciliation or extraction layer is provided to convert noisy outputs into stable shared secrets. Oktay et al. (2024) similarly generate ECG-derived 256-bit outputs for digital watermarking and validate them with a reliability metric rather than requiring exact reproduction. This is compatible with watermark verification tolerance but underscores the mismatch with cryptographic key agreement. Hoque et al. (2008) also faces this limitation. Signature subspace partitioning concatenates the components into a bitstring and does show some resistance to forgery, but the absence of error correction leads to high false rejection and divergence between sessions, limiting its application as a cryptographic key generator.

Mohd et al. (2025) illustrates a different problem, while the work is strong as cancellable template protection, emphasising revocability, non-invertibility, and unlinkability, but the output remains an authentication decision rather than a reproducible secret key, and helper-data leakage is not characterised in the formal secure-sketch sense. In contrast, Sulavko et al. (2025) are closer to an explicit key-generation framing, the authors present a neural fuzzy extractor for voice and report long outputs of 1024 bits, with robust matching performance. However, the deliberate avoidance of stored helper data, motivated by inversion concerns, substitutes one risk for another. The burden of reproducibility shifts to learned stability and system assumptions rather than a standard public helper data with bounded leakage model.

Across these works, the field repeatedly uses the language of key generation while evaluating systems as matchers. However, there is a categorical distinction, verification systems can be valuable, but without an explicit reconciliation or extraction stage they do not satisfy the functional requirements for a cryptographic key.

3.4 Primitive Security Versus end-to-end Security in Biometric key Generation

Even when a design includes strong cryptographic primitives at the key derivation layer, system level assumptions often determine real security. Gorski and Wodo (2024) make this point in their security evaluation of biometric AKE protocols (BAKE/BRAKE). While BRAKE incorporates substantial cryptographic structure including template obfuscation, OPRF-based protections, and a KDF for session keys, the authors identify residual vulnerabilities rooted in key compromise and enforceability. Compromise of evaluator side secrets can enable offline attacks, and assumptions that sensitive values remain only in volatile memory cannot be guaranteed against a rogue client who persists credentials and bypasses biometric presentation. The results emphasise that protocol soundness must be evaluated together with key management, client behaviour, and adversary capabilities.

More broadly, across the surveyed literature the sensor layer is frequently excluded or treated as future work. Voice systems remain exposed to replay and synthesis without liveness or PAD. Face systems evaluated on static datasets lack threat modelling during capture. Iris systems often acknowledge presentation attacks but defer defences and ECG systems sometimes claim inherent spoof resistance without implementing or evaluating formal PAD. Preprocessing layers are typically treated as engineering steps rather than attack surfaces, despite their potential vulnerability to manipulation. Consequently, many schemes concentrate their security reasoning in feature extraction and key derivation while leaving the most deployment relevant attack classes including presentation, replay, and adversarial capture, outside the evaluated system boundary.

3.5 Critical Analysis

Across the surveyed approaches, a common pipeline emerges. Starting from a biometric, a noisy numeric feature vector is extracted. Then an ECC, that ensures small intra-subject variations do not break reproducibility, is applied. Lastly, the corrected vector is hashed to obtain a fixed-length cryptographic key. However, these works generally fall short of Kerckhoffs's principle and do not rigorously evaluate resilience to replay or spoofing attacks. A more formal approach replaces direct mapping b → K with a secure sketch S(b) → s. Given a fresh sample b' close to b, the pair (b', s) reliably reconstructs the same keying material. The helper string s can be stored or made public while leaking only bounded information about b. A fuzzy extractor strengthens this by coupling sketch reconciliation with randomness extraction, ensuring K is both reproducible across noisy measurements and statistically close to uniform (Kuznetsov et al., 2024). Using biometrics as the sole key source faces deeper structural problems. Many biometrics, including biochemical assays, yield only a few dozen bits of entropy, leaving derived keys vulnerable to offline search, population-level inference, and quantum attacks. Biometrics are also not secret, a latent fingerprint, a blood sample, or an intercepted wearable stream exposes the same underlying features. Finally, compromise is permanent: any key deterministically derived from a biometric remains reproducible forever, regardless of how well spoofing is mitigated.

4. Manifold Encryption Key Derivation

The idea of deriving cryptographic keys directly from biometric markers such as bioassays, ECG, fingerprints, and iris prints, is appealing but currently fraught with challenges presented in Section 3. In practice, most systems use biometrics merely as a gate to securely generated keys rather than as the keys themselves.

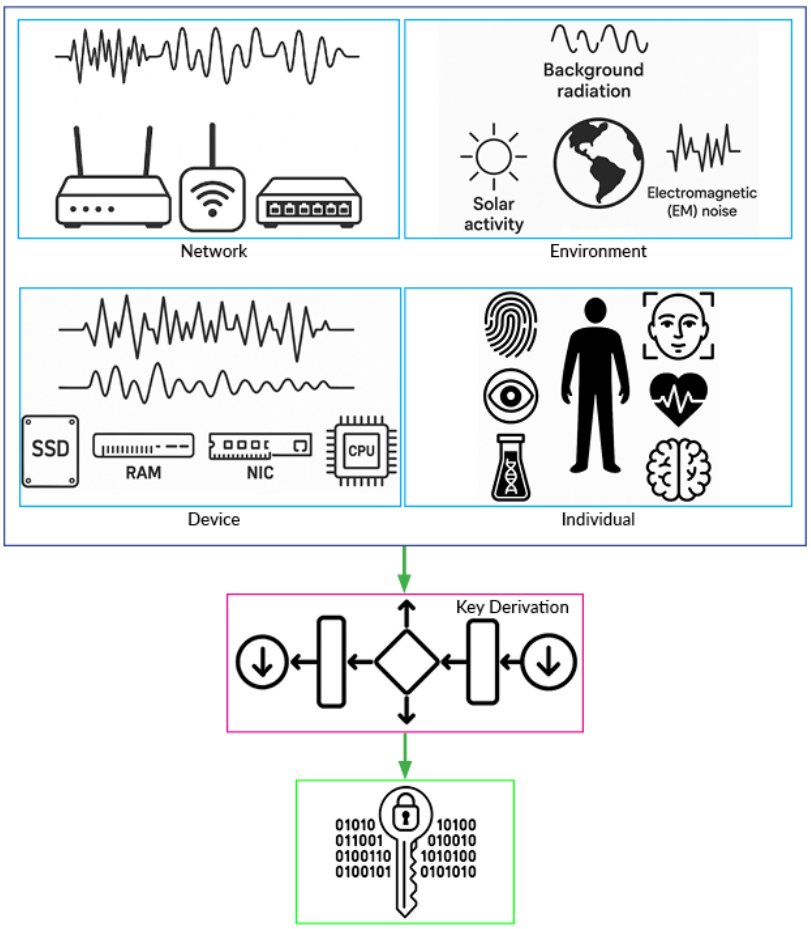

Figure 4: Manifold Encryption Key Derivation

A practical path beyond single modality biometric key generation is to bind biometric traits to signals drawn from the network, environment, and device hardware. For instance, network markers may be derived from topology or hardware identifiers. Environmental markers may include background RF, ambient audio and lighting, temperature, and location. Hardware markers such as CPU, RAM, or SSD fingerprints could be incorporated through challenge-response protocols to further strengthen the binding between identity, device, and context. This proposed manifold encryption key derivation framework is conceptual, but not without precedent. Location has been investigated in continuous authentication architectures for location-based services (Alamleh et al, 2020). Further, beacon frame based two-factor authentication demonstrates how environmental RF signals can serve as an unobtrusive second factor with minimal user involvement (AlQahtani et al, 2020). Additionally, DeMiCPU introduced a robust challenge–response hardware fingerprinting method that leverages magnetic induction signals emitted from CPU modules to capture unique device level discrepancies (Ji et al, 2021).

Encryption keys require careful management, they must be securely stored and if stolen or compromised, the effects can be catastrophic. Ephemeral keys are created, used and then deleted, reducing the attack surface. As the tactics, techniques and procedures of threat actors continue to evolve, implementing ephemeral encryption keys could enhance the protection of mission critical systems, sensitive intelligence and military communication systems.

This multi-domain fusion mitigates the classic weaknesses of unimodal biometrics by binding key derivation to multiple independent contexts. Network and environmental binding limits out-of-context misuse of compromised biometric templates, while hardware anchoring ties key derivation to trusted devices, raising the bar against insider abuse and template attacks. The result is a context-aware, revocable, and device-, location-, and individual-bound key generation scheme, in which compromise of any single domain is insufficient to reconstruct the cryptographic key.

5. Conclusions and Future Research Direction

Security and privacy challenges limit large scale adoption of biometric key generation. Compared with conventional key management, biometric derivation reduces the attack surface associated with stored keys as material is generated on demand rather than persisted, and ties possession to the individual rather than a token or password. However, several fundamental limitations constrain the approach. Measurement noise and intra-subject variability undermine the bit-for-bit reproducibility that cryptographic keys require, and error correction techniques introduced to compensate, reduce effective entropy while the resulting helper data introduces new leakage vectors. Further, many biometric signals carry insufficient entropy to begin with, weakening collision resistance and enabling offline search. Irrevocability compounds this, unlike passwords, biometric traits cannot be rotated, so a deterministically derived key remains reproducible by any adversary who captures the underlying signal. Finally, without robust liveness detection, recorded or synthetic samples enable replay and presentation attacks. These limitations are frequently understated in the literature. Proposed schemes often demonstrate promising entropy or brute-force resistance in controlled settings but lack evaluation under realistic threat models, and the absence of standardised benchmarks makes it difficult to assess robustness and scalability. Without formal proofs and rigorous cryptographic engineering, biometric key generation risks being operationally fragile and in the worst case, a liability rather than an improvement over the approaches it seeks to replace. A practical path beyond biometric key generation is to bind biometrics with complementary, context dependent signals drawn from the network, environment, or device hardware to generate ephemeral encryption keys which dramatically reduces the vulnerabilities of biometrics alone.

mblack@southalabama.edu

Abstract: Industrial automation has brought innovations in efficiency and safety to modern manufacturing. The emergence of big industrial data, AI and Internet-connected industrial automation systems promises many advantages in manufacturing, maintenance, health & safety, product customization, logistics, and reporting. The Industrial Internet of Things (IIoT) seeks to attach industrial systems to the Internet for data collection and processing. The Internet is not a secure place for many of the industrial systems in use today. Industrial networks are designed for speed, accuracy, and availability at the expense of security. In our experiments, we demonstrate how easy it would be for hostile actors to gather data that could be used to compromise the industrial automation systems if actors (a) had physical access to the internal network or (b) access to data streams that feed to the external network. To resolve some of these issues, we propose a hybrid solution of sensor data acquisition in which a secondary network with additional sensors and controllers are installed; the secondary network, sensors and controllers are isolated from the internal control system. The results show that our solution enables useful data collection without impacting the security, speed, accuracy, and availability of industrial control system. It also has the potential to permit anomaly detection using independent sensors on different networks.

Keywords: Sensor networks, Manufacturing, Industry 4.0, Cyber-physical systems, Industrial automation

1. Introduction

Modern industrial manufacturing systems consist of many physical components that perform work to create products. Since the first industrial revolution began replacing people's labour with machines, technological innovations have slowly made their way into manufacturing (Lukač, 2015). The third industrial revolution introduced computing for machine automation, enabling machines to run continuously without human interaction (Adeyeri, 2018). Programmable Logic Controllers (PLCs), considered the heart of these systems, are configured to automatically respond to sensors on the machines and make adjustments to control the process (E. A. Lee & Seshia, 2016). Sensors themselves are read-only devices that measure an analogue or digital value. These values are converted to an electrical signal, amplified, and sent to a controller. Supervisory Control and Data Acquisition nodes (SCADA), collect data from the controllers and save them for trending analysis while providing supervisory control to the processes being controlled by the PLCs (Daneels & Salter, 1999).

Recent research in Industry 4.0 and the Industrial Internet of Things (IIoT) proposes connecting smart automation system data collection devices, called cyber-physical systems, to the Internet (Jazdi, 2014; Lennvall et al., 2017; Sengupta et al., 2020). Research in the proposed Industry 5.0 revolution extends the previous revolution but with more of a focus on sustainability and enhancing human interaction (Demir et al., 2019; Nahavandi, 2019). Traditional automation systems in manufacturing plants were built for dependability, speed, and accuracy at the expense of security, so these devices historically remained attached to an isolated network with minimal services to limit exposure to external threats (Hong & Lee, 2008; Risley et al., 2003). Additionally, automation systems require a specifically designed low-latency network infrastructure for performance and stability (Yan et al., 2021). Adding sensors to this network adds cost and latency, so data collected from them is prioritized for operations and business needs based on value (I. Lee & Lee, 2015).

An automation system's reliability and safety depend on its components' availability. Availability in manufacturing automation systems requires feedback and feedforward methods, including performance monitoring, corrective maintenance, and lifecycle management (Ton et al., 2008). These methods require data, including data collected from the manufacturing system sensors that report the condition of the components.

While many sensors in the manufacturing system are required to give feedback to the manufacturing system for automatic control, some sensors are not used for input into the manufacturing system. Rather than feedback control functions, these sensors collect valuable information for higher-level functions of the

organization, such as predictive maintenance, quality reporting, logistics, system health and performance, environmental compliance, and auditing (I. Lee & Lee, 2015). Since these sensors do not provide feedback control, they need not be connected to the expensive low-latency infrastructure, PLC or SCADA for management. Hence, many of these additional sensors can use more cost-effective non-industrial-grade networking infrastructure, and their systems can be physically isolated from the rest of the manufacturing control systems for security and scalability.

Sensors are read-only measuring devices, but components of the automation control network that rely on the values from these sensors are not. PLCs use sensor values to influence the output of a device in the system. The controller part of a PLC sends signals to energize or make controlled changes to mechanical devices based on the values received from sensors and the logic programmed into them. SCADA systems collect and store data from these PLCs and can write values to the memory of the PLCs to affect changes in the manufacturing process. This process of continuous sensor reading and adjustment is called a feedback loop. The PLC and SCADA systems, which are not read-only devices, are vulnerable to cyber-attacks and must be protected. Advancements in IIoT and cloud connectivity will require changes in manufacturing system configuration to minimize the risk of compromising system security.

In this paper, we conduct an experiment that adds additional sensors to an existing industrial control system for data collection, isolating these sensors from the current feedback control sensors. The data collected from the additional sensors is recorded into a separate system, which is then analysed to gain alternative insights that were unobtainable without the additional sensor data. The data was then compared with the internal sensor data to gain insights into the operation of the industrial control system devices. The experiment concludes by validating that the any malfunction with the additional sensors will not reduce the availability of the existing control system.

The remainder of this paper is organized as follows. Section two presents the background in industrial automation and introduces the concepts in IIoT. Section three presents our methodology. Section four presents our experiment of modifying an isolated cyber-physical network by adding a separate sensor network developed for this research. The results of the experiments are presented in Section five. Section six discusses and concludes this research.

2. Background

2.1 Adding Automation in the Industrial Revolution

Beginning in the early 1970s, the third industrial revolution introduced electronic automation systems to the mechanized processes provided by the first two industrial revolutions (Adeyeri, 2018). Automation was designed to make decisions and monitor processes with little human intervention. These systems increased efficiency by removing the human element from repetitive tasks and replacing them with autonomous machines that could run continuously. At the most basic level, an automation system consists of 4 physical components (Abbate, 2000; Roberts, 1978; Ton et al., 2008):

- A device that causes something to happen, such as a motor that drives movement, an actuator that opens a valve, or a heating element that causes a change in temperature
- A sensor that measures the changes that are happening to the device, such as a flow meter, temperature sensor, or limit switch
- A controller device that collects the sensor information, calculates a measured value and generates a response that loops back to the device.
- Infrastructure to connect the physical components

Combined, these physical elements create a process control loop at the heart of industrial automation.

2.2 Industry 5.0

A fifth industrial revolution promises to add additional intelligence to the processes and increase the synergy between humans and machines. Where Industry 4.0 sought to automate the process to eliminate as much human interaction as possible, Industry 5.0 aims to have tasks requiring high levels of creativity be performed by a human, leaving the remaining tasks to automation systems better suited for them (Sehrawat & Gill, 2019; Weis, 2010). The automation systems of Industry 5.0 also seek to increase reliance on AI, big data, and cloud computing to support new functions, such as additive manufacturing, predictive maintenance, and intelligent product customization. These additions will require an increase in the number and type of sensors collecting

data, contributing to a greater volume, velocity, and variety of data (Lennvall et al., 2017; Sehrawat & Gill, 2019).

2.3 Industrializing the Internet of Things

Traditional sensors in industrial automation systems generate data to provide feedback to the automation system and record data for trending and quality control purposes (Boyes et al., 2018). These sensors are expensive to implement because each sensor requires an input channel on a PLC, infrastructure for the connection to the PLC, engineering design and development of the PLC program to implement the feedback logic, a SCADA license for control and data collection, and supporting computer hardware and software. A cost-effective industrial control system collects only the data required to run the industrial processes and produces the needed quality analysis and regulatory information.

Industrial automation control systems were designed for low-overhead, low-latency operations. To reduce the risk of external influence on internal control systems, protection of the control network is implemented at the perimeter, which typically follows a standard security model such as the popular Purdue Enterprise Reference Architecture (Boyes et al., 2018; Williams, 1994). This model segments networks into zones separated by restrictive firewalls to create an isolated control network that carefully controls access to this network. While this protects the network from outside influence, it complicates expansion and serviceability when new technology replaces failed or outdated systems.

Where the Internet of Things sought to use sensors to detect the movement of objects, the Industrial Internet of Things (IIoT) aims to implement the scalability and logistical benefits into the industrialized business setting. Since these types of sensors do not need to be industrialized, connected to a PLC, or be required to provide feedback for automation and control, they are a candidate for separation from the industrial control system. This separate sensor and data collection system can be configured to eliminate interference with the existing feedback control sensors and their associated data collection systems.

3. Methodology

For our research, an experiment was conducted that analyses the security issues when exposing an industrial control system network to an external, uncontrolled network. The results from this experiment were used to conduct a second experiment that uses a separate, read-only sensor network attached to the external, uncontrolled network, leaving the industrial control system network secured in its closed network.

In the first experiment, a second computer on the control network was used to conduct a series of network scans and packet captures to view the raw traffic on the control network. This computer will represent a threat actor that has gained access to the control system network. With this experiment, the scans were used to map devices and discover points of weakness in the system.

A second experiment was conducted that isolates the control network from the uncontrolled network. Existing industrial devices were configured with a secondary read-only sensor connected to a separate network that can be safely exposed to an external, uncontrolled network for data collection. This experiment consisted of four parts.

In part one of the second experiment, data was collected using the existing sensors, PLCs, and SCADA systems on the isolated network already in place. A pre-set task was executed on the control system to generate feedback data from the PLC, and the data was stored on the SCADA computer. This data was used as control data and compared with data collected by the sensors on the external network in part three.

In part two of the second experiment, additional sensors were installed on the controlled devices to collect information from the same device. These additional sensors were then connected to a separate computer to read their signals. This computer does not provide any output control to any devices. The pre-set task was again executed on the control system to generate feedback data from the PLC and stored on the SCADA. The data collected from this task was compared to the control data from part one.

In part three of the second experiment, data collected from the separate sensor system was examined and compared to the control data. Although the sensors are designed to collect the same information as the remote sensors, the sensor types were different so the values did not match exactly. The parameters for the new data set were adjusted to compensate for these differences, then compared with the data collected from part one.

A threat actor was introduced to the uncontrolled network in part four of the second experiment. The same threat actor computer used in experiment one was attached to the uncontrolled network with the secondary, read-only sensors. The data was then analysed and compared the results to the packets collected in experiment one.

4. Experiment

For our experiments, we used a power plant simulator training system that contains an Allen Bradley CompactLogix PLC with input/output cards in a rolling cabinet, shown in Figure 1. On top of the cabinet is a diorama of a small town designed to emulate a power plant and distribution of substations, shown in Figure 2 (next page).

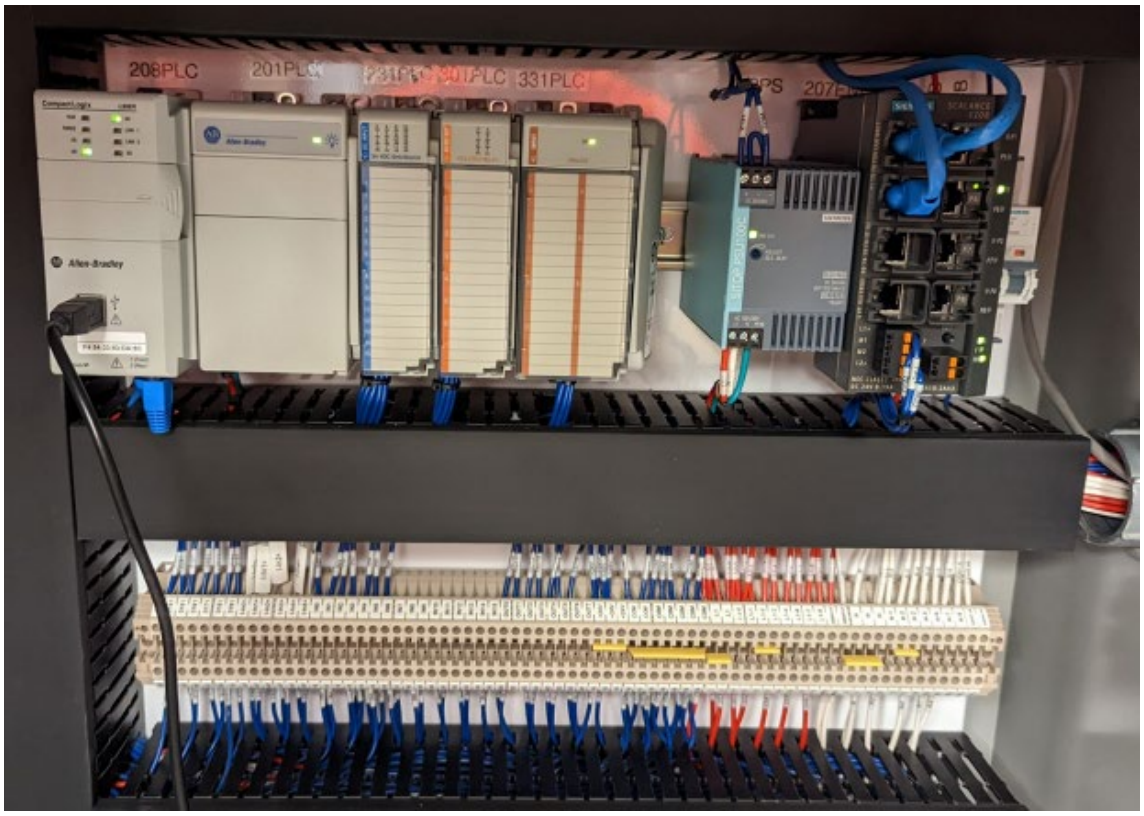

Figure 1: Allen Bradley CompactLogix PLC chassis

Next to each substation is a red and green light emitting diode (LED) and an analogue meter. The LEDs represent the status of the substation as either energized or not energized, and the analogue meters represent the power load at each substation. A variable resistor next to the power plant is used for input and represents the power load placed on the power generation plant. The LEDs are attached to the PLC digital output card. The analogue meters are connected to the PLC analogue output cards to simulate a change in the load of each substation. The variable resistor is attached to the PLC input card.

The PLC is connected via Ethernet to a Seimens SCALANCE X208 industrial network switch connected to a Windows 10 PC. This PC runs Allen Bradley ControlLogix software for programming the PLC and includes a Human-Machine Interface (HMI) program and a SCADA development and runtime environment. The PLC and the Windows PC are the only devices attached to this network switch. The Windows PC is not connected to any other network, and all devices on the industrial switch remained isolated on their network during the experiment.

A relay was manually activated in the control system software running on the SCADA computer to execute the task on the power plant simulator. The power plant simulator represents this by turning on the green LED light next to the substation. The circuits are designed to turn off the red LED when the green LED is turned on. This indicates the simulated substation has been activated.

Figure 2: Power plant simulator

Experiment one, illustrated in Figure 3, used a second computer attached to the Seimens network switch to act as the threat actor that has gained access to an internal computer on the control network. A standard laptop running Kali Linux was used. This laptop was connected to the Seimens network switch and was not attached to any other network during this experiment. A packet capture of the control network switch was performed using Wireshark to examine the communication packets between the PLC and the SCADA computer. The substation switchover task on the power plant simulator was executed and recorded the data on the SCADA machine and the packet capture from Wireshark.

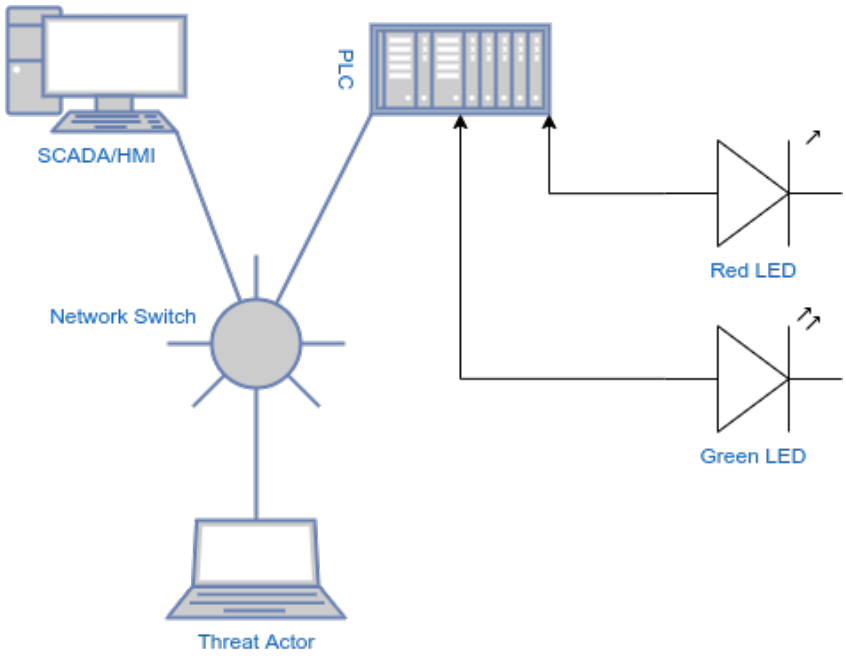

Figure 3: Configuration for experiment one

The packet capture data of the conversation between the SCADA computer and the PLC was analysed. The data included packets that carried information from the PLC to be written to the SCADA database, as well as

commands from the HMI to the PLC to activate the relay to trigger the execution of the substation switchover task on the power plant simulator. This concluded experiment one.

A new data sample was first taken from the PLC and SCADA system for experiment two. The substation switchover task was executed, and the time was manually recorded while the data was collected on the SCADA. The data collected was verified and matched to the manually recorded timeframe. This concluded part one of experiment two.

In preparation for part two of the second experiment, the threat actor was removed from the internal network. The separate sensor network was prepared by adding external sensors to the power plant simulator. The external sensors consist of photoresistors, which will detect the switchover of a substation by registering a change in the light intensity of the LEDs on the diorama. Since the LEDs are acting as a digital device on the PLC to represent on and off, and the photoresistors are an analogue device, it will be necessary to adjust the parameters of the output data of the photoresistors to compensate for the differences in the digital data of the LED's when comparing the on and off values to analogue integer values.

Two photoresistors were placed in proximity to the LEDs of a substation, as shown in Figure 4. The photoresistors were attached to the analogue input ports of an Arduino microcontroller, as shown in Figure 5. The Arduino was programmed to detect variations in light intensity and write them as an integer value to the serial buffer every half second. The Arduino was able to detect the brightness and record it as an integer value.

The Arduino controller collects data but cannot store it, so it was connected to a Raspberry Pi 400 via USB to store the collected data. A simple Python program was developed for the Raspberry Pi to collect the data from the Arduino every second, adding a timestamp field and appending the data to a CSV file on the micro-SD card inserted into the Raspberry Pi. The Arduino performs a function similar to the PLC. The Raspberry Pi in this case performs a function similar to a SCADA Historian database.

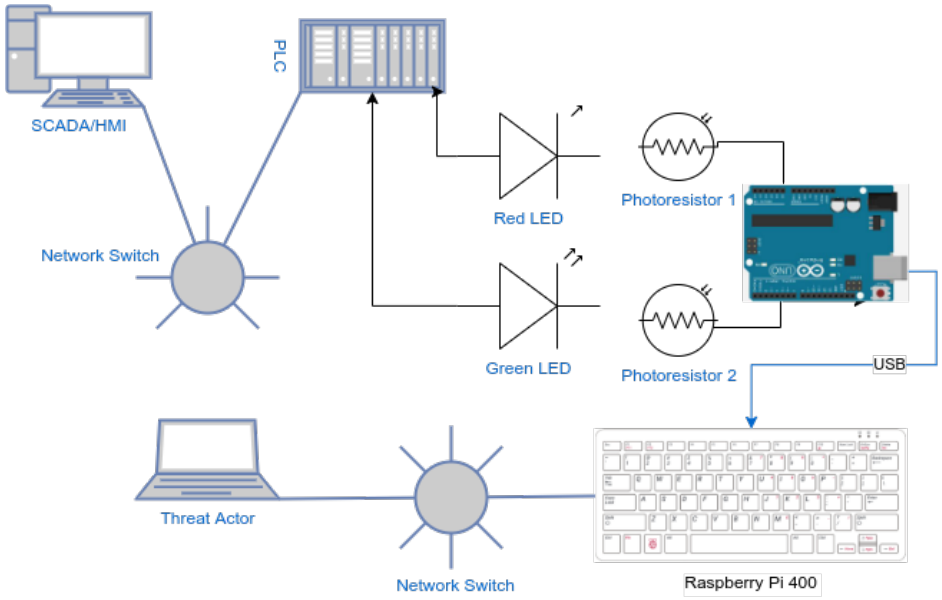

Figure 4: Configuration for experiment two

The Arduino was powered on, and the Raspberry Pi was booted up in preparation for part two of the experiment. Once the Python application was started and connected to the Arduino, the same substation switchover task from experiment one was executed and the time was manually recorded. The still visible LEDs made their change to indicate a successful switchover. The Python program was stopped after 300 seconds, concluding the test. The data collected from the Arduino was saved to a CSV file on the Raspberry Pi, and a quick check was performed to verify there was data in the file. This concluded in part two of the second experiment.

Part three of the second experiment required the data set collected from the SCADA computer in experiment one and the data set collected from the Raspberry Pi in experiment two. The data sets were exported as CSV

files and saved to a flash drive for analysis on a separate machine. The Results section presents the findings of the comparison of the data sets. This concluded part three of the second experiment.

In part four of the second experiment, we reintroduced the threat actor to the additional sensor network to determine if the threat actor would be able to carry out the same kind of attacks on both networks. The same laptop used in experiment one was connected to the same network as the Raspberry Pi and began capturing packets with Wireshark. The Python program was executed to collect the external sensor data, and the same substation switchover task was executed. The results section presents the findings of the network data that was collected. This concluded part four of the second experiment.

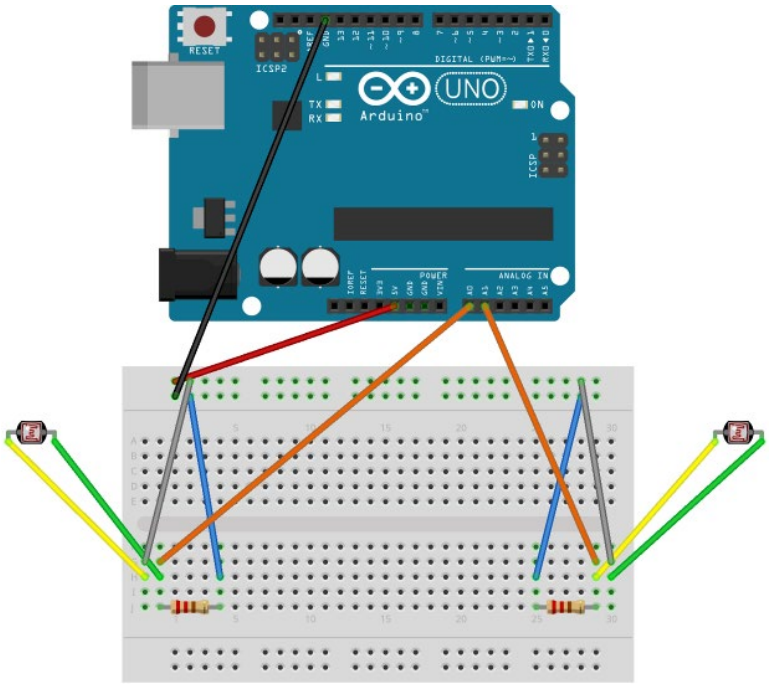

Figure 5: Arduino with photoresistors

5. Results

Experiment one was a controlled experiment to analyse the network traffic of a control system to understand the weaknesses of the system. A threat actor with access to this level of the control system network would be able to carry out attacks that could cause systems to go offline through a denial of service attack or cause substantial damage to any cyber-physical devices by intercepting packets between the PLC, HMI, and SCADA systems and modifying the commands or generating new ones (Wardak et al., 2016).

In experiment one, data was collected from the PLC during the execution of a task that caused a red LED to turn off and a Green LED to turn on. The Wireshark capture of the network packets displayed the data collected from the event. The packets sent from the SCADA/HMI computer to the PLC showed the event request to perform the switchover to the substation in the power plant simulator. The packets sent from the PLC to the SCADA/HMI computer showed the response to the request so the HMI could be updated, and the SCADA recorded the change in the database. The date and time manually recorded at the beginning of the event matched the data collected from the event and stored in the SCADA database. This created our control database for comparison.

For experiment two, the control system network remained isolated as it was designed. Additional sensors were added to the devices to create a separate sensor network. The HMI and data collection to the SCADA PC remained unaffected by the addition of the sensors. The LEDs in the diorama remained visible since the photosensors did not block their view but were only in proximity.

The Raspberry Pi and Arduino successfully collected data from the photoresistors in the power station diorama and saved the data to a local CSV file. The CSV file contains 301 timestamped records that were recorded over 300 seconds.

Since the photoresistors are analogue sensors that send an integer value based on the light intensity, the values recorded to the CSV file had to be tuned for each photoresistor to determine an LED's digital on or off event in the diorama. In Figure 6, the blue line labelled A1 is the analogue input of the photoresistor for the Green LED, and the digital output equivalent for the same Green LED is the yellow line labelled D1. Likewise, the red line labelled A2 and the green line labelled D2 are the analogue and digital outputs for the Red LED, respectively. The LEDs in the diorama were not shining at the same colour or intensity. Also, ambient light around the LEDs could change intensity based on the surroundings, such as the status of the lights in the lab or the shades on the windows being open during daylight hours. The Y-axis values of Figure 6 account for this tuning, with a 0 representing a digital "off" value and 900 representing the digital "on" value to accommodate the variability in the light coming from the analogue photo resistors. The highest analogue value of A2 peaked at 880 from the Arduino. This tuning of the data parameters was also performed manually through several lighting condition experiments. Once the values were tuned to determine the proper integer ranges for the light intensity of an on-and-off condition, a formula was added to LibreOffice Calc for two additional columns to determine the on-and-off status of the LEDs. After tuning, the data reliably showed the timeframes of the LEDs turning on and off compared to the observations made during experiment two.

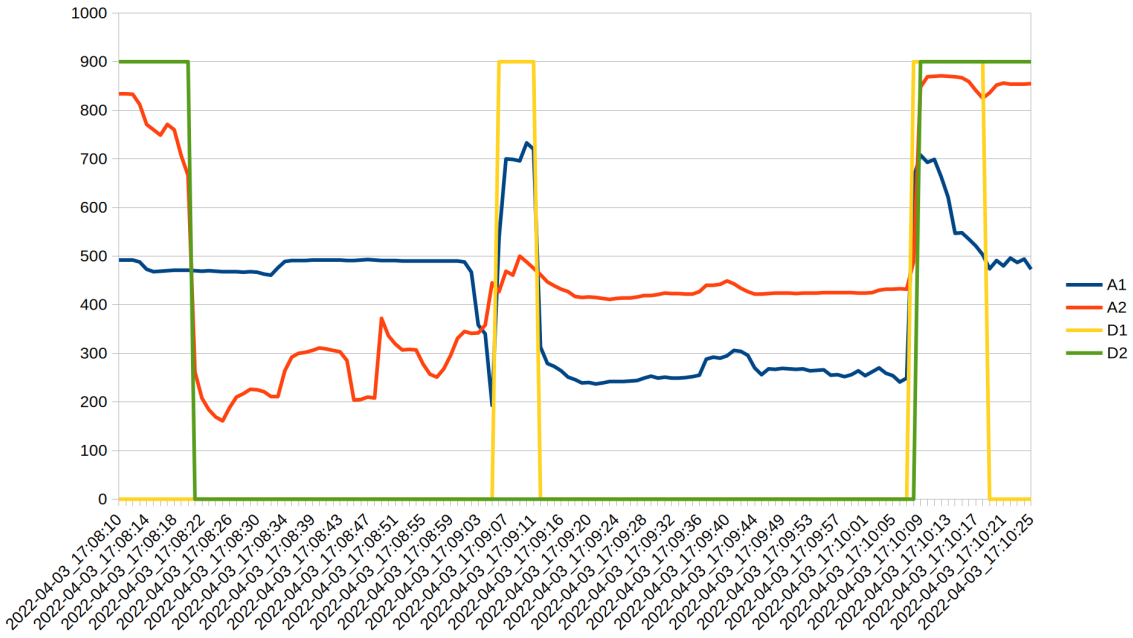

Figure 6: Data collection and results converted to digital output

After the analogue data parameters from the external sensor network were tuned, the data was compared to the binary values of the internal sensor network. The values matched and were time synchronized with the recorded date-time stamps and the manually recorded time. The results shown in Figure 6 indicate that the external sensor system can record sensor data reliably while remaining independent of the internal sensor system.

The additional step of exposing the threat actor to the secondary sensor network did not disclose any internal or external sensor data via a Wireshark capture due to the way the devices were connected and used. The threat actor at this level could modify data or cause denial of service, but this would not affect the PLC operation and would be detectable when comparing the data between the two sensors. However, this experiment was not complete since the data saved to the Raspberry Pi was not transmitted over the network. In production environments, the data would likely not remain on the edge device, such as this Raspberry Pi, but would be processed and sent to another storage location, such as a cloud server. In this case, the threat agent could capture the sensor data from the external sensor network. Although the data collected from the external sensors is a representative facsimile of the internal sensors, they remain physically isolated, which is the point of this experiment. A threat actor would not be able to affect devices or data generated from the internal sensor network.

6. Conclusion and Perspectives

While in the initial stages, this research completes one step for future research in implementing IIoT in manufacturing that current research still needs to identify. Separating sensors on the same networking equipment using Virtual Local Area Networks (VLANs) to reduce latency and group network devices is not unusual. Still, this experiment uses physically isolated networks to separate the PLC feedback data from non-critical data-collecting sensors.

Manufacturing plants that follow the Purdue Enterprise Reference Architecture model for securing the sensor networks against external attacks may find this hybrid solution an acceptable alternative to opening their sensor network for outbound Internet connectivity. Their sensitive sensor networks remain in managed isolation, and they can take advantage of the benefits of IoT sensors with no feedback capability to the automation system. Should this exposed sensor network be compromised or taken offline, it will not affect the operation of the critical internal systems.

Future research will explore using the extra sensor data to validate the data from internal sensors used in the feedback loop. The Stuxnet worm caused PLCs to perform a destructive physical operation on manufacturing devices, then lie to the SCADA system to cover up what was happening (Kriaa et al., 2012). Had a system like our proposed system been in place, data from internal sensors could be compared to data from external sensors using anomaly detection algorithms and alert someone to the discrepancy. Since the two sensor networks are physically separated and could consist of different types of components, the attacker would have to compromise both systems for the attack to be hidden successfully.

Ethics Declaration: Ethical clearance for this research was not required.

AI Declaration: No AI of any kind was used in the creation of this paper.

Abstract: This paper outlines the need for security on the smart grid, specifically for Phasor Measurement Units (PMUs) and Phasor Data Concentrators (PDCs). These devices are targeted due to their criticality to the smart grid and the insecure communication protocols used. Common attacks on these devices target the data sent between them. As such, integrity-based attacks are the focus of this paper, more specifically on False Data Injection attacks (FDIAs) and Time Synchronisation Attacks (TSAs). Security solutions are proposed throughout literature from mitigation and protection techniques to detection and resolution techniques. To secure the PMU and PDC, this paper proposes an authentication protocol, utilising Physically Unclonable Functions (PUFs). PUFs are utilised to ensure device-specific authentication, in addition to the use of other cryptographic techniques including fuzzy extractors, nonces, encryption algorithms, and identifiers. A testbed was developed, on which the protocol was implemented and tested against the integrity-based attacks, namely FDIA and TSA. Informal and formal security analyses were performed on the protocol, finding that the protocol was secure against multiple attacks, including the FDIA and TSA, and implemented mutual authentication and forward secrecy. The formal security analysis was implemented with Proverif, a software used to prove the security of authentication protocols. The informal security analysis is provided as a logical sequence to prove the protocol's security against attacks and inclusion of security proofs. A performance analysis was performed to ensure the protocol had low enough computation, communication, and storage overheads.

Keywords: Authentication, Phasor measurement unit, Physically unclonable function, Phasor data concentrator, False data injection, Time synchronisation attack

1. Introduction

The International Energy Agency reports that the transmission sector of the smart grid grew by 10% in 2023 globally. The transmission sector is responsible for grid monitoring, transforming, and transmitting energy (IEA, 2025). Phasor Measurement Units (PMUs) are vital to grid stability as the devices provide monitoring of the grid and calculate an estimation of the state of the grid. The data includes current, voltage, frequency, and rate of change of frequency, also known as synchrophasor data. These data are passed to another device, the Phasor Data Concentrator (PDC), which checks the integrity of the synchrophasor packets and aligns the packets via timestamp, vital for state estimation (Paramo et al., 2022). The PMU and PDC are connected within the smart grid for bidirectional communication, making up the Wide Area Management System (WAMS) (Paramo et al., 2022), pictured in Figure 1. The PMU and PDC can communicate through different protocols, the main one being a plain-text protocol, IEEE C37.118 synchrophasor protocol. Due to the nature of plain-text protocols, devices communicating become susceptible to multiple vulnerabilities, for instance cyber-attacks (Cheng et al., 2023).

Common attacks targeting message integrity include data spoofing, injection, and replay attacks (Hasan et al., 2024). Confidentiality and availability are targeted with attacks such as Man-In-The-Middle (MITM) and Denial of Service (DoS). Other attacks that can impact the WAMS include Time Synchronisation Attacks (TSAs) and physical attacks (Nazir et al., 2025). False Data Injection Attacks (FDIAs) and TSAs are two attacks that can cause large impacts on the system (Sanati and Kamwa, 2023). Due to these attacks, security solutions are proposed in literature to safeguard systems. These solutions include authentication, encryption, key distribution schemes (KDSs), and digital signatures. These solutions focus on creating keys, identities, and cipher-text to mitigate attacks (Anantharaman et al., 2018, Hussain et al., 2022). Machine learning (ML) is another solution proposed for mitigation of cyber-attacks but can also be utilised for detection. ML techniques have been used to improve intrusion detection systems, existing authentication systems, and securing the data collected from smart grid devices (Nayak et al., 2023).

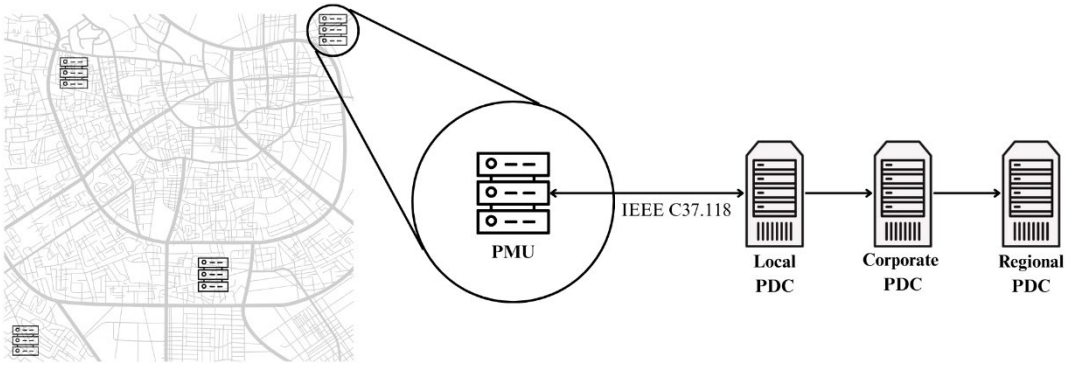

Figure 1: Basic WAMS layout demonstrating the communication between devices

Existing literature proposed solutions to secure the communication between PMU and PDC and its data. These solutions include security filters (Anantharaman et al., 2018), KDSs (Hussain et al., 2022, Farooq et al., 2023), ML (He et al., 2022), and data source authentication (Cui et al., 2021). All these solutions focus on securing the devices in different ways, for example, KDSs create a shared session key between devices. Security filters focus on detecting attacks within the network by searching the communications. Data source authentication methods detect spoofing attacks by checking the data for any modifications.

The goal of this paper is to propose an authentication protocol that can protect PMU and PDC communication against attacks, while achieving mutual authentication and creating a shared session key. The aim of the protocol is to specifically secure against FDIAs and TSAs since they can cause a large impact on the system. The authentication will prevent the FDIAs and TSAs while keeping the communication fast and reliable. The main contribution of this paper is an authentication protocol and analyses, including informal, formal, and performance. The protocol utilises Physically Unclonable Functions (PUFs) amongst other cryptographic techniques to achieve mutual authentication. A weak and a strong PUF are utilised as well as encryption, hash functions, XORs, nonces, and timestamps. The informal security analysis reveals the protocol to mitigate against, FDIA, TSA, replay, DoS, and physical attacks. The formal security analysis is performed with Proverif, indicating the protocol is secure. The performance analysis calculates the performance, outlining low computation, and small communication and storage overheads. The rest of this paper is formatted as follows: Section 2 covers the related works; Section 3 outlines the background; Section 4 outlines the proposed protocol; Section 5 describes the implementation of the protocol on a testbed; Section 6 provides the analyses; and Section 7 concludes this paper.

2. Existing Literature

Some existing works propose authentication protocols and other techniques for securing PMUs and WAMS. Anantharaman et al. (2018), created a security filter for IEEE C37.118 to parse frames to distinguish between the current message and previous messages. The purpose of their filter, PhasorSec, is to identify and remove any packets that may have been compromised. Their work mentions the fact that FDIAs are not protected against with PhasorSec, although their protocol could be extended with other techniques, to protect against such attacks.

Two papers create security solutions like KDSs to secure the PMU data when communicating between devices. Message authentication codes and certificate authorities are utilised in one scheme, testing the scheme on an experimental setup to find the size of the synchrophasor packet is impacted. This scheme is created to mitigate against attacks on IEEE C37.118 (Hussain et al., 2022). The following scheme is created to secure data and authenticate devices using the IEC 61850-90-5 communication protocol. This scheme is tested against TLS 1.2 and 1.3, finding 1.3 to be more efficient (Farooq et al., 2023). Neither of these papers record attacks secured by the proposed schemes. Two papers utilised existing techniques to secure PMU data and communications. Qiu et al. (2012) use cryptographic algorithms to secure communications of PMU and smart meters (SMs). While He et al. (2022) use existing ML methods to authenticate PMU data. They found that Continuous Wavelet Transforms with Convolution Neural Network performed the best. Javed et al. (2024) proposed a data provenance protocol that uses PUFs and quantum principles. The attack focused on within the security analysis was MITM attack. Hussain (2026) created a security scheme that makes use of digital signatures across IEEE C37.118. Performance analysis is calculated; however, a full security analysis is not performed. Table 1 outlines

the above papers, the techniques used to secure PMUs, the attacks mentioned within the paper to be secured, and the security proof claimed within the paper.

Table 1: Proposed authentication protocols in recent literature

Reference	Techniques	Attacks	Proofs
(Anantharaman et al., 2018)	Frame Filter	AFL Fuzzer	N/A
(Hussain et al., 2022)	Certificates, Key Distribution, Encryption, Hash Functions	N/A	Confidentiality, Integrity
(Qiu et al., 2012)	Encryption	N/A	Increased Energy Efficiency
(Farooq et al., 2023)	Key Distribution, Certificates, Encryption	N/A	Improved Security, Performance
(He et al., 2022)	Machine Learning	N/A	Accuracy, Predict Time, Pre-process Time
(Javed et al., 2024)	Hash Functions, PUFs, Quantum Unreality, Quantum Uncertainty	MITM	Privacy, Unpredictability
(Hussain, 2026)	Signatures, Hash Functions, Encryption	N/A	Message Integrity
This paper	Hash Functions, XOR PUFs, Encryption, Fuzzy Extractor	FDIA, TSA, Replay, DoS, Physical	Mutual Authentication, Forward Secrecy

The following papers all propose methods for synchrophasor data source authentication. The algorithms are created to protect against data spoofing attacks by detecting modifications in the data source information. Different ML and deep learning algorithms are utilised to achieve the data source authentication. Existing methods include “Mathematical Morphological Decomposition and Multi-Weighted Deep Stacking Forest” (Cui et al., 2022), “Multiscale Adaptive Coupling Correlation Detrended Analysis” (Bai et al., 2023), Quadratic Kernel Support Vector Machine (Liu et al., 2022b), “Self-Adaptive Mathematical Morphology and Time-Frequency” (Cui et al., 2021). While these papers help to secure the PMU data, they are not achieving the same communication security as proposed in this paper.

3. Background

The smart grid consists of different systems to generate, distribute, and transmit energy and information. There are two main systems for monitoring the energy distributed across the grid and they are Supervisory Control and Data Acquisition (SCADA) system and WAMS. The SCADA system utilises devices such as intelligent electronic devices or remote terminal units to gather grid data. The SCADA reports at a rate of every two to five seconds, reporting active/reactive power information such as power injections and flows, they also report on voltage magnitudes. The WAMS monitors the voltage, current, frequency, and rate of change of frequency, and consists of PMUs and PDCs. The PMUs report anywhere between five to 60 data scans every second. The PMUs capture this information from the grid and pass this data onto the PDC. The PDCs then collate this data, ordered by time, and either analyse the data or transfer it onto the next PDC. Some PDCs have the capability to analyse the synchrophasor data, while others simply collate, align, and store the information (Cheng et al., 2023). The communication focus of this paper is between the PMU and PDC.

3.1 Communication of PMU and PDC

There are two main protocols that have been used for synchrophasor communication, the first was IEEE 1344, which was replaced by IEEE C37.118 in 2011 (Grewal et al., 2014). The IEEE C37.118 protocol is the focus for this paper due to its popularity. The protocol uses TCP as a base, consists of five fields within the header, and has three frame types. The configuration frame is sent at the beginning of communication between the PMU and PDC to outline the structure of the data frame. The command frame contains information instructing the PMU of an action, for example, sending configuration frame or starting data transmission. The data frame has seven fields and sends the data collected from the grid. The data frame is the main frame needing to be secured as it is transferring energy information in plain-text across the network. Figure 2 shows the fields of the IEEE C37.118 protocol.

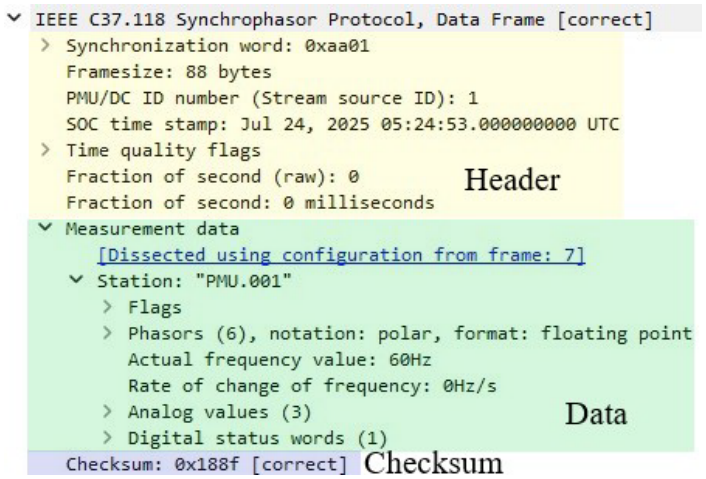

Figure 2: Wireshark capture of IEEE C37.118 data frame

The IEEE C37.118 communication protocol is wrapped with TCP/IP, thus when the PMU sends synchrophasor data the PDC sends back an acknowledgment.

3.2 Vulnerabilities of IEEE C37.118

An adversary that gains access to the smart grid network, can view the synchrophasor data being sent across the network. Many attacks can be targeted towards the communication between the PMU and PDC, impacting the confidentiality, integrity, or availability of the grid. Confidentiality is impacted when the adversary gains access to the network and views the data being sent, for example, MITM. Integrity is impacted when the data being passed across the network is modified or removed, such as a FDIA (Sanati and Kamwa, 2023). Availability is impacted when the system is shut down, such as a DOS. The most common attacks mentioned in recent literature includes, MITM, FDIA, spoofing, DOS, and replay attacks (Amanlou et al., 2025). The attack focus of this research is FDIAs and TSAs. TSAs can impact the performance of the system and cause incorrect actions to be taken by misguiding operators (Zhang et al., 2013). FDIAs situational awareness of the smart grid through modifying PMU data measurements (Sanati and Kamwa, 2023).

4. Proposed Protocol

This section outlines the authentication protocol, describing the components, and the different phases.

4.1 Preliminaries

4.1.1 Physically unclonable functions

PUFs are typically sorted into two categories, strong and weak. A strong PUF is defined as a security parameter that can grow to be quite large. If the PUF does not have this capability, then it is considered weak (Armknecht et al., 2011). Weak PUFs are typically used as keys while strong PUFs used for authentication. However, strong PUFs are susceptible to ML attacks, while weak PUFs are not (Santiago et al., 2017). Therefore, for the proposed protocol, we utilise both PUFs. The protocol makes use of one weak PUF, PUF_W and one strong PUF, PUF_S. The PUF_W is used as the key for encryption during the authentication phase of the protocol. PUF_S and PUF_W are used as part of the session key for encryption once the PMU and PDC have been authenticated. The PUFs require a challenge to output a response, the equation is written as: $PUF_X(Ch_X) = R_X$.

4.1.2 Fuzzy extractor

The protocol uses fuzzy extractors to ensure the noise from the response does not impact the protocol. The fuzzy extractor uses generation and reproduction algorithms. Generation is run first to get the helper data, hd_X, and the key, K_X. The generation algorithm for the fuzzy extractor is written as: $FE.Gen(R_X) = K_X, hd_X$. The reproduction algorithm is run each time a stored response is retrieved or regenerated to dissipate the noise and get the K_X. The reproduction algorithm is written as: $FE.Rep(hd_X, R_X) = K_X$.

4.1.3 Other cryptographic primitives

The protocol employs other cryptographic techniques to strengthen the security. These techniques include, hash functions, XORs, nonces, and timestamps. Timestamps are used to ensure the messages do not go through

another path on their transit to the other device. Hash functions, XORs, and nonces are used to make the messages difficult to interpret by an adversary. The protocol also utilises an encryption algorithm to securely send data between the PMU and PDC.

4.2 Authentication Protocol Phases

The proposed authentication protocol is made up of two phases, namely, initialization and authentication. The initialization phase generates initial challenge, response, and helper data to be stored with the PDC and PMU. The authentication phase allows the devices to create a shared session key allowing for encryption.

4.2.1 Initialisation phase

This phase sends the challenge to the PMU through a secure channel, with the response used with the fuzzy extractor generation algorithm to store the helper data at the PMU. The PMU ID, response, challenge, and helper data are all sent to the PDC through a secure channel. Figure 3 shows the steps for the initialisation phase.

Algorithm 1 – Name of Protocol – Initialisation Phase
PDC_x:
Challenges, Ch_s and Ch_w are generated.
Challenges are sent to the PMU via a secure channel.
PMU_y:
Strong response is calculated $R_s = PUF(Ch_s)$
Strong helper data, hd_s, and key is calculated, $FE.Gen(R_s)$
Weak response is calculated $R_w = PUF(Ch_w)$
Weak helper data, hd_w, and key is calculated, $FE.Gen(R_w)$
PMU retrieves its own ID, ID_y.
Helper data is stored.
Challenges, responses, helper data, and ID is sent to the PDC via a secure channel.
PDC_x:
Challenges, responses, helper data, and ID is stored.

Figure 3: Algorithm of initialisation phase of proposed protocol

4.2.2 Authentication phase

The authentication phase is initiated every time communication between the PMU and PDC is requested. This phase results in a shared session key between the PMU and PDC allowing for the PMU data to be encrypted. To mutually authenticate, verifiers are used to confirm the identity of each device, while timestamps are used to ensure the communication has not been intercepted on transit. The session key is created from components used throughout the phase. Figure 4 shows the steps for the authentication phase.

5. Implementation

The testing of the proposed authentication protocol was performed by implementing the protocol on a testbed. This section discusses the testbed, the attacks on the testbed, and the protocol performance.

5.1 Testbed

The testbed was formed to view, attack, and protect the IEEE C37.118 protocol. The PMU and PDC are formed from simulators, on a Raspberry Pi (RPi) and Dell PC, respectively, and communicate using a wired connection through a router. Other components include two other RPis that launch an attacker and a time server. The first stage was to set up the communication between the PMU and PDC, ensuring the two devices were communicating via IEEE C37.118. Once this communication was established, the time server was added to grab the time via GPS and pass that time onto the PMU and PDC devices through the Network Time Protocol (NTP).

Algorithm 2 – Name of Protocol – Authentication Phase	
PDC_x	**PMU_y**
Timestamp, T_1, and nonce, r_1, are generated.	
Challenges, Ch_w, Ch_s, Helper data, hd_w, hd_s, Responses, R_w, R_s, and ID_p are retrieved from storage.	Timestamp, T_2, and nonce, r_2, are generated.
	Helper data, hd_w, hd_s, retrieved from storage.
Nonce share, N_1 is calculated by $ID_p \oplus r_1$	ID_p is retrieved and hashed, ID_h
Key, K_w, is produced with the fuzzy extractor, $FE.Rep(hd_w, R_w) = K_w$	$ID_h \oplus H_1$ to get Ch_w
	Response, R_w is calculated $PUF(Ch_w)$
Message, M_1, is created with the encryption algorithm and K_w, $E_{Kw}(T_1 \mid N_1 \mid Ch_s)$	Key, K_w is calculated with $FE.Rep(hd_w, R_w)$
	M_1 is decrypted, $D_{Kw}(M_1)$ to get T_1, N_1, Ch_s
Hashed message, H_1, created by $h(ID_p) \oplus Ch_w$	T_1 is checked against T_2, if too far apart, messages may be intercepted, communication terminated.
M_1 and H_1 are sent to the PMU_y	
	Response, R_s is calculated $PUF(Ch_s)$
	Key, K_s is calculated with $FE.Rep(hd_s, R_s)$
	Nonce, r_1, is retrieved by $ID_p \oplus N_1$
	Verifier 1, V_1, is formed with $h(K_s \mid ID_p \mid r_1)$
	Message 2, M_2, is created with the encryption algorithm and K_w, $E_{Kw}(r_2 \oplus ID_p \mid V_1 \mid T_2)$
	M_2 is sent to the PDC_x
Timestamp, T_3, is generated.	
M_2 is decrypted, $D_{Kw}(M_2)$ to get T_2, V_1, H_2	
T_2 is checked against T_3, if too far apart, messages may be intercepted, communication terminated.	
	Timestamp, T_4, is generated.
Key, K_s is calculated with $FE.Rep(hd_s, R_s)$	M_3 is decrypted, $D_{Kw}(M_3)$ to get N_2, T_3
V_1, is verified by PDC_x calculating $V_1' = h(K_s \mid ID_p \mid r_1)$ and comparing V_1 and V_1'	T_3 is checked against T_4, if too far apart, messages may be intercepted, communication terminated.
H_2 is xored with ID_p to get nonce, r_2	
Verifier 2, V_2, is formed with $h(r_2 \mid ID_p \mid r_1)$	$N_2 \oplus r_2$ to get V_2
Message 3, M_3, is created with the encryption algorithm and K_w, $E_{Kw}(V_2 \oplus ID_p \mid T_3)$	V_2, is verified by PDC_x calculating $V_2' = h(r_2 \mid ID_p \mid r_1)$ and comparing V_2 and V_2'
Session Key, SK, is created $h(r_2 \mid ID_p \mid K_w \mid K_s)$	Session Key, SK, is created $h(r_2 \mid ID_p \mid K_w \mid K_s)$
Message 4 is created to obtain new strong challenge, $E_{SK}(Ch_{sx})$	M_4 is decrypted, $D_{SK}(M_4)$ to get Ch_{sx}
	New s-response is calculated $R_{sx} = PUF(Ch_{sx})$
M_3, M_4 are sent to the PMU_y	New helper data, hd_{sx}, and key is calculated, $FE.Gen(R_{sx})$
	M_5 is created with SK, $E_{SK}((R_{sx}, hd_{sx}) \oplus r_1)$
	M_5 is sent to PDC_x
Ch_{sx}, R_{sx}, hd_{sx} are stored.	

Figure 4: Algorithm of authentication phase of proposed protocol

5.2 Attacks

The attacks on the testbed were set up using a Python script to intercept the plain-text traffic. The attacks that were chosen were FDIA and TSA. The first attack to be implemented was the TSA. A Python script for NTP spoofing was retrieved online from GitHub. This script was modified to work with the devices and the testbed network. This attack targeted the communication between the time server and the PMU, to modify the PMU's time. Modifying the time incorrectly ordered the measurements when collated by the PDC. The FDIA was next, and this was implemented by modifying the script for the NTP spoofing attack. The attack targeted the plain-text within the IEEE C37.118 protocol to modify the frequency that was recorded by the PMU. The frequency was modified in between the PMU and PDC, so the PMU reported the correct value, but the incorrect value reached the PDC.

5.3 Experimental Analysis

The protocol was developed in Python, with scripts in between the two simulators. The scripts would listen for the devices and when they connected the authentication protocol would be run. If the protocol was successful in mutual authentication then the simulators could connect, and the data was encrypted with the shared session key. If the verification was not mutually successful, the script would terminate communication. The FDIA was unable to be executed as the synchrophasor data was encrypted. The TSA failed as the authentication protocol checks timestamps, if the PMU time was changed the authentication protocol would terminate.

6. Protocol Analysis

6.1 Informal Security Analysis

6.1.1 False data injection attacks

The objective of the adversary in a FDIA is to modify data as it is passed across the network to make the receiving device misjudge the data. Since the PMU and PDC communicate bi-directionally, the adversary can target either communication from PDC to PMU or PMU to PDC. However, the protocol utilises encryption and hash functions, so if the adversary modifies the data being sent, the messages will not be decrypted properly. If the verifier gets modified the protocol will end communication since the verifiers do not match. Thus, making the FDIA unsuccessful.

6.1.2 Time synchronisation attacks

The objective of the adversary in a TSA is to misguide communications and information by modifying the timestamp of a device. The synchronisation of PMUs is vital to measure phasor data across multiple PMUs. However, the authentication protocol uses timestamps to check the validity of the messages, so if the timestamps are modified, communication will be disconnected. Thus, making the TSA unsuccessful.

6.1.3 Other attacks

The objective of the adversary when executing a replay attack is to send previously sent messages to gain access to the device. However, the protocol implements the use of rotating keys and nonces, so if an old message is sent to either device, communication will be terminated based on incorrect data being received. Thus, making the replay attack unsuccessful. The objective of the adversary during a DoS attack is to send so many messages to an entity on a network that the computation power is overtaken, and they cannot receive the legitimate messages sent. Since the authentication protocol terminates communication if a message comes through that is incorrect, the DoS attack will be unsuccessful. The objective of the adversary in a physical attack is to physically gain access to the device through proximity rather than remotely. With the use of PUFs, the PMU is not at risk if physically apprehended since the PMU does not store the responses from the challenges. Thus, making the physical attack unsuccessful.

6.1.4 Security criteria

Mutual authentication is the process of the devices authenticating one another. This is vital for the PMU and PDC communication since they communicate to each other. The verifiers in the protocol allow for this. The verifier for the PMU is the hash of $h(K_S, ID_P, r_1)$, the key and nonce are different each time the protocol runs, so the verifier cannot be recorded. The verifier for the PDC is the hash of $h(r_2, ID_P, r_1)$, both nonces change each iteration of the protocol, so the verifier cannot be recorded. Forward secrecy means that if the session key is obtained by an adversary, it does not reveal anything about future session keys or is not a future session key. The session key of this protocol is the hash of $h(r_2, K_S, ID_P, K_W)$, the contents of the session key cannot be revealed as they are securely hashed; the nonce and keys are changed each iteration of the protocol so the session key cannot be recorded.

6.2 Formal Security Analysis

This section outlines the use of a software that confirms secrecy of protocol variables and verifies the protocol's ability to confirm values that are received. Proverif is based on the Dolev-Yao model that allows users to write out the logic for their authentication protocol to prove values are kept secret throughout communication. There were three variables we did not want the attacker to learn while the protocol was running. They were the ID and the two PUF responses, weak and strong. In the Proverif logic, we queried these variables to ensure their secrecy would not be impacted during the protocol's runtime. Proverif was also used to ensure the two devices authenticated one another, Firstly, in the logic, by ensuring the event of the PDC authentication occurred after the PMU started authentication (and vice versa); secondly, with a query to make sure that anytime the PDC accepts a message from the PMU there is a prior occurrence of the PMU sending the exact message (and vice versa). The Proverif logic was run to find that the attacker cannot learn the PMU ID, or responses of the PUFs, the main sources of secrecy. The other piece of information confirmed in Proverif was that the PMU and PDC authenticated one another properly, and the timestamps were accepted correctly. Figure 5 shows the verified outcome from Proverif.

```
------------------------------------------------------------
Verification summary:

Query not attacker(ID) is true.

Query not attacker(Rw[]) is true.

Query not attacker(Rs[]) is true.

Query inj-event(BAuthed) ==> inj-event(AStarted) is true.

Query inj-event(AAuthed) ==> inj-event(BStarted) is true.

Query inj-event(B_accepts_T(x)) ==> inj-event(A_sends_T(x)) is true.

Query inj-event(A_accepts_T(x)) ==> inj-event(B_sends_T(x)) is true.

------------------------------------------------------------
```

Figure 5: Verification summary from Proverif

6.3 Performance Analysis

6.3.1 Execution time

The computation time was recorded within the Python script, however due to Python's low computational power, these numbers were heightened significantly. The cryptographic primitives such as XOR and hash functions are recorded normally, but the cryptographic algorithms such as fuzzy extractor are much larger. Since these cryptographic algorithms are not recorded as in a real-world scenario, execution times as recorded by other papers are used (Liu et al., 2022a, Kaveh et al., 2023, Hussain et al., 2022). Figure 6 shows the final times as a combination of times recorded by Python for the primitives and normalised times based on other papers for the techniques.

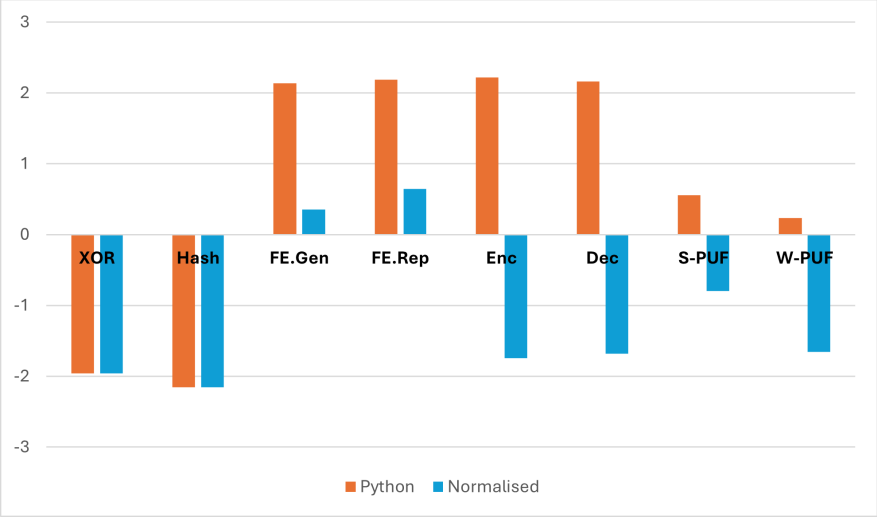

Figure 6: Logarithmic execution times of cryptographic techniques, Python vs normalised

6.3.2 Communication overhead

The communication measurement was calculated based on the number of bits sent over the course of the protocol. Figure 7 outlines the bits for each message sent across the protocol. The total bits are calculated based on the size of the messages sent, calculated from the cryptographic primitive sizes. The total size for all messages totalled to 200 bytes.

6.3.3 Storage overhead

The storage overhead is only calculated for the PMU device, since the PMU is the storage constrained device. The only things the PMU needs to store is the helper data for the strong and weak PUFs. The helper data, amounts to 16 bits each, making the total storage cost for the PMU is 4 bytes.

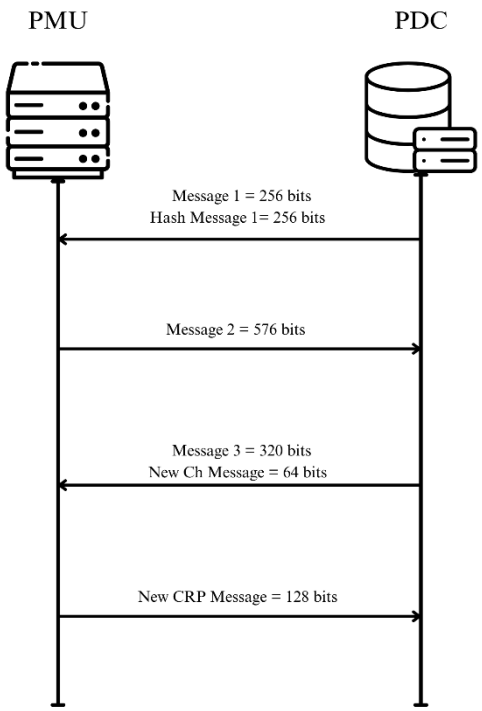

Figure 7: Messages in bits sent between devices

7. Conclusion

PMUs are vital devices for the smart grid to estimate the current state of the grid. They report the data of the grid to the PDC through a plain-text, insecure communication protocol. This makes the devices vulnerable to cyber-attacks, such as FDIAs and TSAs. This paper proposes an authentication protocol to protect the devices against such attacks. The protocol utilises PUFs to ensure the PMU does not have to store much data or use too much computational power. The protocol is analysed through a formal and informal security analysis and a performance analysis. It is found that the protocol is secure against multiple attacks, verifiably secure, and lower on computation, communication, and storage costs.

The CTI Oligopoly's Contractual Firewall: Restrictive Licensing as a Structural Barrier to Collective APT Defence

Raymond Andre Hagen
Norwegian University of Science and technology (NTNU), Norway

Raymond.Andre.Hagen@digdir.no

Abstract: Cyber threat intelligence (CTI) is widely promoted as indispensable for modern cyber defense, yet collective defense in practice is constrained by market concentration and restrictive licensing imposed by a small number of dominant vendors. This study analyses 34 publicly available documents; licence agreements, terms of service, API documentation, and pricing materials, across 15 major commercial CTI providers. Following a thematic analysis approach, we code restrictions across six dimensions: (1) access pathways and subscription gating, (2) redistribution and collaboration rights, (3) automation interfaces and rate limits, (4) portability and interoperability, (5) pricing transparency and contract flexibility, and (6) geographic and jurisdictional constraints. Findings confirm a highly concentrated oligopolistic market in which the top five to ten vendors control an estimated 50–80% of global revenue and a disproportionate share of APT telemetry. Recent consolidation, including Mastercard's USD 2.65 billion acquisition of Recorded Future in December 2024, further reinforces this concentration. Licence terms systematically prohibit redistribution to third parties, constrain automation through non-cumulative quotas and unstable APIs, and obscure pricing behind enterprise sales funnels. These patterns constitute what we term a *contractual firewall*, a structural barrier that prevents threat intelligence from flowing between defenders even where policy frameworks encourage sharing. The contractual firewall creates asymmetries in defensive capability that disproportionately affect SMEs, public-sector entities, and sector consortia. These constraints do in some instances conflict with European collective defense mandates like NIS2, but fundamentally fragment the defender ecosystem, leaving smaller entities vulnerable to sophisticated threat actors. We suggest some procurement-focused recommendations for redistribution carve-outs, export and portability requirements, API stability guarantees, and multi-source resilience strategies. Future work should validate these patterns against negotiated enterprise terms and assess operational impact in incident response environments. We conclude that resource-constrained defenders facing APTs are caught in a systemic double bind: the 'contractual firewall' restricts the intelligence access necessary for pro-active defense, while regulatory frameworks like NIS2 impose sharing mandates that these commercial restrictions effectively render impossible to fulfill.

Keywords: CTI, Threat intelligence, AI

1. Introduction

Cyber threat intelligence (CTI) is widely marketed as the missing component that makes detection and response effective at scale. In practice, CTI is embedded in complex socio-technical systems where information must be shared, integrated, and acted upon in real-world defensive workflows.

This paper investigates whether publicly available materials from commercial CTI providers, including license agreements, terms of service, API documentation, and pricing information, reveal patterns of market concentration and how these patterns affect collective defense against

APTs. It examines constraints across six operationally relevant dimensions: (i) access pathways and subscription gating, (ii) redistribution and collaboration rights, (iii) automation interfaces and rate limits, (iv) portability and interoperability, (v) pricing transparency and contract flexibility, and (vi) geographic and jurisdictional constraints.

Based on these dimensions, the paper demonstrates that the CTI market exhibits a set of systemic barriers that are incompatible with mandates for collective defense, such as those reflected in the EU NIS2 Directive (NIS2). (European Union, 2022)

The analysis is limited to publicly accessible documents captured between January and October 2025 and does not assess detection efficacy or indicator quality.

Contribution. The paper contributes three elements: (i) a conceptual framing of a "contractual firewall" as a systemic barrier to CTI sharing, (ii) an empirical analysis of 15 leading providers based on public documents, and (iii) practical procurement guidance aimed at mitigating lock-in and enabling collective defense.

To structure the investigation, we pose three research questions:

RQ1: What patterns of market concentration are visible in the commercial CTI landscape based on publicly available contractual and technical materials?

RQ2: How do access terms, redistribution rights, and automation constraints influence the practical use of CTI in operational security processes?

RQ3: What are the implications of these patterns and terms for European collective defense and policy goals, such as those reflected in the EU NIS2 Directive (NIS2)? (European Union, 2022)

Structure of the paper. Section 2 provides background and defines the scope; Section 3 reviews related work; Section 4 describes the method; Section 5 presents the main findings; Section 6 discusses practical and policy implications; Section 7 offers recommendations for procurement teams; Section 8 addresses limitations and future work; Section 9 concludes.

2. Background and Scope

Commercial cyber threat intelligence (CTI) supports organizations by providing indicators of compromise (IoCs), actor tracking, detection logic, and contextual analysis. It is positioned as a crucial layer for defending against advanced persistent threats (APTs) which are long-lived, cross-border by nature, and often exploit asymmetries between national and commercial defenders.

At the policy level, European frameworks increasingly emphasize information sharing and cooperative resilience. The EU NIS2 Directive (Directive (EU) 2022/2555) strengthens obligations for incident reporting, risk management, and cross-sector cooperation, and it encourages voluntary information-sharing arrangements (Article 29). (European Union, 2022)

This paper focuses on the intersection between these policy aims and the commercial CTI market. It treats licensing terms, access pathways, and technical integration constraints as first-order determinants of whether organizations can participate effectively in collaborative defense.

3. Related Work

The intersection of commercial CTI markets and collective defense has received limited systematic attention in the academic literature, though related threads of research inform this study.

3.1 CTI Quality and Operationalization

Research on CTI quality has established frameworks for evaluating intelligence outputs. Schlette et al. (2020) developed metrics for measuring and visualizing CTI quality, highlighting the gap between raw indicators and actionable intelligence. Böhm et al. (2018) introduced graph-based visual analytics approaches for CTI, enabling analysts to identify patterns across large indicator sets. More recently, Chatziamanetoglou and Rantos (2025) proposed weighted quality criteria for CTI assessment within the MISP data model, demonstrating ongoing efforts to standardize evaluation.

Systematic reviews have mapped the broader CTI landscape. Saeed et al. (2023) establish that organizational cybersecurity resilience depends critically on timely access to high-quality threat intelligence, a dependency that becomes problematic when access is constrained by commercial terms. Aboelfotoh et al. (2025) examine the role of artificial intelligence in enhancing threat detection, noting that AI-driven capabilities are increasingly concentrated in well-resourced commercial platforms.

3.2 Information Sharing and Collective Defense

The theoretical case for threat intelligence sharing rests on classic public goods arguments: threat information is non-rivalrous and exhibits positive externalities when shared. CISA's evolving approach emphasizes "threat-informed cybersecurity" enabled by rapid dissemination (Cybersecurity and Agency, 2023). Similar principles underpin sectoral sharing organizations (ISACs) and coordinated disclosure frameworks (Alliance, 2025). The MITRE framework for world-class security operations centers identifies threat intelligence integration as a core capability (MITRE, 2022), yet assumes access to quality intelligence sources without examining the contractual barriers that may prevent such access.

3.3 Market Structure and Policy Frameworks

The global threat intelligence market has attracted significant analyst attention. Multiple market reports estimate 2025 valuations between USD 6–15 billion with double-digit growth rates (MarketsandMarkets, 2025; Research, 2025b; Intelligence, 2025; Insights, 2025). Industry analyst reports consistently identify a small set of dominant vendors (Research, 2025a; Gartner, 2025; Exabeam, 2025), but systematic analysis of how their contractual terms affect collective defense remains scarce.

European policy frameworks increasingly mandate information sharing and cooperative resilience. The EU NIS2 Directive (Article 29) encourages voluntary cybersecurity information-sharing arrangements, while Article 21 requires essential entities to implement risk management measures that implicitly depend on access to timely threat intelligence (European Union, 2022). The ENISA Threat Landscape provides annual assessments of the evolving threat environment (ENISA, 2025), and the World Economic Forum highlights the widening gap between well-resourced and under-resourced defenders (Forum, 2025).

This policy-market tension, where mandates assume shareable intelligence while commercial terms prohibit sharing, forms the empirical focus of our analysis.

4. Method

We conducted a document analysis of 34 publicly accessible documents covering 15 commercial CTI providers, following a thematic analysis approach (Braun and Clarke, 2006). Data collection occurred between January and October 2025.

4.1 Material Collection

Commercial CTI providers were identified using a combination of industry reports, market ana-lyses, and public directories, including Gartner Magic Quadrant for Security Threat Intelligence Services, Forrester Wave for External Threat Intelligence, and vendor aggregators (Gartner, 2025; Research, 2025a; G2, 2025; Capterra, 2025). Providers were selected based on market prominence, visibility in European procurement, and availability of publicly accessible licensing documentation. The selection focused strictly on dedicated CTI products, excluding generalist cybersecurity firms lacking specific intelligence offerings. Table 1 lists the analyzed providers.

Data collection was conducted manually, utilizing exclusively publicly accessible documents (licence agreements, terms of service, datasheets, API documentation, and pricing pages where available) retrieved via direct website navigation without authentication or paid access. Document types were limited to those detailing CTI features, contractual terms, and technical specifications.

4.2 Inclusion and Exclusion Criteria

Inclusion and exclusion criteria were defined to ensure relevance and reproducibility, aligning with established practices in cybersecurity systematic reviews (Saeed et al., 2023; Aboelfotoh et al., 2025).

Included: Provider-facing materials published or updated within the study window that ex-plicitly address the six operational dimensions: access pathways, redistribution rights, automation interfaces, portability/interoperability, pricing transparency, and geographic constraints.

Excluded: (1) Non-public or customer-only materials; (2) evaluations of technical detection efficacy; (3) reverse engineering of content or APIs; (4) unverifiable claims not grounded in documents; and (5) general marketing materials lacking specific contractual terms (Aboelfotoh et al., 2025; Böhm et al., 2018).

4.3 Analysis Procedure

The analysis followed a structured, multi-stage workflow resembling an expansion-contraction model, designed to manage the complexity and volume of the dataset (Braun and Clarke, 2006). **Phase 1: Domain Scoping and Selection.** Initially, we established a baseline understand-ing of the CTI landscape through a review of general industry reports and market definitions.

This phase focused on identifying key market players and establishing the six operational dimen-sions for analysis, effectively framing the scope before engaging with the high-volume vendor documentation.

Phase 2: Corpus Expansion and Deep Analysis. The core analysis involved a significant expansion in data volume, ingesting 34 specific vendor documents (licenses, API references, pricing models). Given the density of this legal and technical material, we employed digital text analysis tools to cross-validate findings across the vendor pool. This "all-against-all" verification ensured that identified restrictions were not isolated anomalies but systemic patterns within the oligopoly.

Phase 3: Normative Synthesis. Finally, the analysis converged by mapping the validated vendor constraints against specific problem-oriented frameworks, primarily the EU NIS2 Directive and CISA sharing guidelines. This phase focused on interpreting the operational impact of the identified restrictions specifically within the context of collective defense mandates.

5. Findings

5.1 Market Structure and Concentration Signals

Multiple market intelligence reports estimate the global CTI market in 2025 at USD 9–17 billion and growing at high single to double-digit rates (MarketsandMarkets, 2025; Research, 2025b;

Intelligence, 2025; Insights, 2025). Across these reports, the top vendors are consistently ranked with a substantial share of revenue concentrated in a small set of providers. Estimates vary but commonly place the top five to ten vendors at 50–80% of global revenue (MarketsandMarkets, 2025; BitSight, 2025).

The functional implication is that a limited number of platforms control high-volume telemetry, actor tracking, and APT narrative framing. Smaller vendors and community feeds exist (Flare, 2023), but their coverage, automation maturity, and historical depth are limited. Table 1 summarizes the analyzed providers and their restriction patterns.

Table 1: Analyzed CTI Providers and Key Restriction Patterns

Provider	Redistribution	API Limits	Pricing	HQ
CrowdStrike	Prohibited	Rate-limited	Opaque	US
Recorded Future[a]	Prohibited	Quota-based	Opaque	US
Palo Alto Networks	Prohibited	Rate-limited	Opaque	US
Microsoft Defender TI	Limited	Tiered	Partial	US
Mandiant (Google)	Prohibited	Rate-limited	Opaque	US
IBM X-Force	Prohibited	Rate-limited	Opaque	US
Cisco Talos	Prohibited	Rate-limited	Opaque	US
Fortinet FortiGuard	Prohibited	Bundled	Opaque	US
ThreatConnect	Prohibited	Quota-based	Opaque	US
Rapid7	Prohibited	Rate-limited	Partial	US
Group-IB	Prohibited	Negotiated	Opaque	SG[b]
EclecticIQ	Limited	Configurable	Opaque	NL
Sekoia	Limited	Tiered	Partial	FR
Anomali	Prohibited	Rate-limited	Opaque	US
Intel 471	Prohibited	Negotiated	Opaque	US

[A]Acquired by Mastercard (December 2024, USD 2.65B). [B]Relocated headquarters from Russia to Singapore.

5.2 Recent Market Consolidation

Market concentration intensified during 2024–2025 through significant acquisitions. Most notably, Mastercard completed its USD 2.65 billion acquisition of Recorded Future in December 2024, absorbing what had been characterized as "the world's largest threat intelligence company" with over 1,900 clients across 75 countries, including governments of 45 nations and more than half of the Fortune 100 (MarketsandMarkets, 2025). This transaction exemplifies how CTI capabilities are being absorbed into larger financial and technology conglomerates, potentially further consolidating market power and raising questions about long-term pricing and access terms.

5.3 Access Pathways and Subscription Models

Non-trial access to full-featured CTI is directed exclusively through enterprise sales funnels and annual commitments (CrowdStrike, 2025b; Future, 2024). Trial offerings, where available, are generally restricted in scope: limited time, limited content, sometimes community feeds only, and lacking API access or historical data (Microsoft, 2025).

Contractual rigidities create further barriers: minimum contract commitments commonly range from 12 to 36 months, often with automatic renewal clauses (CrowdStrike, 2025c; Future, 2025b). This economic gating is reinforced by explicit messaging that distinguishes large enterprises from SMEs already at the marketing layer.

5.4 Redistribution and Collaboration Rights

Analysis of the license agreements confirms a near-universal restriction on sharing CTI content with third parties, including sector peers, joint ventures, subsidiaries, and external coordination mechanisms. Representative clauses (verbatim or near-verbatim) include:

- Recorded Future (Terms v7.0, Oct 2025): "Customer shall not ... disclose, [...] or use for the benefit of any third party" (Future, 2025b).
- CrowdStrike Falcon Intelligence Terms (2025): "non-exclusive, non-transferable, non-sublicensable license for internal business purposes only" (CrowdStrike, 2025c).
- Palo Alto Networks End User Agreement (2025): "You shall not ... transfer the Software except in accordance with Palo Alto Networks license transfer procedure" (Networks, 2025).
- IBM X-Force Exchange Terms (2025): "Sharing outside of the licensed organization is prohibited unless expressly authorized in writing. (IBM, 2025)"

In practice, these restrictions hinder the creation of shared sector baselines, shared indicator repositories, and defensive collaboration in multi-organization incident response, precisely the activities encouraged under NIS2 Article 29 (European Union, 2022).

5.5 Automation Interfaces and API Constraints

Even where APIs exist, access is often rate-limited, quota-constrained, and governed by terms that restrict automated redistribution, scraping, or bulk extraction (CrowdStrike, 2025a; Future, 2025a; ThreatConnect, 2025). Observed constraints include:

- Hard rate limits and credit-based quotas that reset monthly and cannot be carried over, inhibiting essential retrospective analysis.
- Pagination and query complexity limits that make bulk historical retrieval impractical.
- Schema changes without deprecation periods. Recorded Future and CrowdStrike reserve the right to modify APIs "at any time", increasing integration cost and operational risk (Future, 2025a; CrowdStrike, 2025a).

These patterns make CTI integration less like a stable infrastructure dependency, and more like a fragile vendor-controlled interface.

5.6 Pricing Transparency and Contract Flexibility

Pricing transparency for full-featured CTI offerings is minimal. Procurement teams face "contact sales" funnels and non-disclosed bundles, making it difficult to compare offers and assess switching costs. The only transparent pricing signals found were:

- CrowdStrike Falcon Go (SMB bundle) —USD 59.99/user/year (limited intelligence) (Crowd-Strike, 2025b),
- Microsoft Defender TI Standard —free (community feed only) (Microsoft, 2025),
- Rapid7 Threat Command —"starting at" figures on request pages (Rapid7, 2025).

All other vendors rely on negotiations. Renewal terms and uplift structures can exceed 15–20%, creating budget uncertainty and long-term commitment pressure.

5.7 Geographical and Regulatory Constraints

The market is dominated by U.S.-jurisdiction providers: every large vendor in the sample is U.S.-based or falls under U.S. export control regimes, requiring careful consideration by non-American users regarding data sovereignty and regulatory compliance.

The lack of jurisdictional diversity is notable: based on our document analysis, none of the examined vendors offered a regionally hosted instance of their full CTI platform, forcing defenders to rely on a single legal framework for critical intelligence processing. The two European providers in our sample (EclecticIQ, Sekoia) offer more flexible terms but lack the telemetry depth of their U.S. counterparts.

5.8 Systemic Implications for APT Defence

Taken together, the evidence demonstrates that the commercial CTI market embeds a structural access asymmetry: it concentrates high-value telemetry and actor narratives in a handful of vendors, restricts

redistribution, limits automation, and exhibits opacity around pricing and contract structure. This asymmetry is repeated across contract patterns and technical terms, conflicting with mandates for coordinated, cross-border information sharing (European Union, 2022).

The implications extend beyond individual organizations: when CTI cannot flow between defenders, the ecosystem loses network effects that would otherwise strengthen collective resilience, while threat actors face no equivalent constraints on sharing among themselves (Center for Strategic and International Studies, 2022).

6. Discussion

The preceding analysis indicates what we define as a CTI oligopoly is characterized by concen-trated access, restrictive redistribution rights, and integration constraints. These constraints are not merely legal formalities; they have operational consequences for incident response and collective defense.

6.1 Contractual Firewall as a Coordination Barrier

A contractual firewall emerges when organizations are legally and technically prevented from sharing CTI outputs with trusted peers, sector partners, or coordinating institutions. This firewall is reinforced by non-portable data formats, non-transparent pricing, and asymmetric renewal structures.

The concept parallels established observations in cybersecurity economics: information asymmetries between attackers and defenders are well-documented (Center for Strategic and International Studies, 2022), but less attention has been paid to information asymmetries *among* defenders created by commercial licensing. Where attackers freely share tools, techniques, and target information through underground forums, defenders face contractual prohibitions on equivalent collaboration (ENISA, 2025). The contractual firewall thus represents a structural disadvantage that policy frameworks alone cannot resolve without addressing the underlying market dynamics.

6.2 Implications for SMEs and Public-Sector Defenders

For SMEs and public-sector entities, high subscription costs, limited trial access, and lengthy minimum contract terms can prevent entry into full-featured CTI ecosystems (Forum, 2025). These organizations may remain dependent on community feeds and ad hoc sharing, creating capability gaps relative to large enterprises.

This observation reveals a duality: smaller defenders understand the need for CTI, but lacking economic power, they attempt to build capabilities independently, incurring substantial costs in personnel and skill reallocation that might be more productively deployed in day-to-day security operations. The World Economic Forum has highlighted this widening gap between well-resourced and under-resourced defenders as a systemic risk to global cybersecurity (Forum, 2025).

The implications extend to national security. Public-sector entities responsible for critical infrastructure protection may find themselves unable to access the same intelligence available to private-sector peers, or unable to share threat information received under restrictive licenses with other government agencies (Cybersecurity and Agency, 2023).

6.3 Policy Tension and Cooperative Resilience

NIS2 Article 29 encourages voluntary information sharing and cooperative resilience, specifically enabling exchange of “cyber threats, near misses, vulnerabilities, techniques and procedures, indicators of compromise, [and] adversarial tactics” (European Union, 2022). However, the commercial baseline terms documented here restrict precisely these forms of redistribution and inhibit the development of sector-level shared baselines.

This creates a structural tension: European policy assumes that entities can share threat intelligence within trusted communities, while commercial contracts prohibit such sharing. Organizations complying with vendor terms may inadvertently undermine the cooperative security posture that NIS2 seeks to establish.

Furthermore, since APT actors are sophisticated and employ diverse tactics across campaigns (Gan et al., 2023; Splunk, 2025), effective defense often requires correlating intelligence from multiple sources. Organizations subscribing to a single vendor may develop incomplete threat pictures, potentially creating a false sense of security by addressing only the risks visible through their available intelligence sources. The documented restrictions may thus fragment the defender ecosystem precisely where unity would provide the greatest advantage.

7. Recommendations and Actionable Guidance

Based on the observed contractual and technical constraints, we believe these restrictions can significantly reduce an organization's ability to defend against APTs. We also acknowledge that commercial interests are integral to the specialized CTI market; nonetheless, we offer recommendations that may improve organizational APT defence posture, recognizing that some provisions may be difficult to negotiate in procurement processes.

7.1 Possible advisories for procurement teams and security leaders:

1. **Redistribution carve-out for defence:** Permit sharing of indicators, detections, and analytical findings with trusted partners for defensive purposes, aligning with NIS2 Article 29 information-sharing provisions (European Union, 2022).
2. **Explicit export and portability:** Require bulk export in structured formats, including historical data, with defined frequency and without punitive fees (Alliance, 2025).
3. **API stability and change control:** Include minimum notice periods for breaking changes, versioning guarantees, and rate-limit terms that support automation at scale.
4. **Interoperability commitments:** Require documented integration paths to SIEM/SOAR/EDR tooling, with clear terms for connector usage and third-party enrichment.
5. **Pricing and exit transparency:** Make pricing units, overage costs, and data-retention or egress costs explicit, and require an end-of-contract export clause that remains valid after termination.
6. **Jurisdiction and data residency:** Specify geographic restrictions, data residency options, and any limitations on cross-border operational use of CTI outputs.
7. **Operational minimums:** Define minimum deliverables to better implement the CTI platform output into your security operations.
8. **Multi-source resilience:** Where feasible, design for at least one secondary CTI source or community feed to reduce single-vendor dependency and to have the possibility to correlate multiple CTI sources.

8. Limitations and Future Work

This study relies on publicly available documents, so it cannot capture negotiated enterprise agreements, NDAs, or operational practices that may materially alter the baseline constraints reported here. Large enterprises may secure more favorable terms than the public baselines suggest; conversely, smaller organizations may face even stricter conditions. Additionally, while conservative coding practices were applied to mitigate ambiguity, the qualitative nature of thematic analysis involves a degree of subjective interpretation (Braun and Clarke, 2006).

We do not assess detection efficacy, indicator quality, or comparative product performance, dimensions that would require access to operational environments and controlled testing (Schlette et al., 2020). The corpus reflects a fixed time window (January–October 2025), and terms and interfaces can change with limited notice, as explicitly permitted in several of the analyzed agreements.

Future work should (i) compare public baselines with negotiated contracts under controlled access, (ii) validate operational impact through case studies of CTI use in incident response and information-sharing workflows, (iii) conduct longitudinal monitoring of licensing and API com-mitments to quantify stability over time, and (iv) examine whether recent market consolidation affects pricing and contractual flexibility for existing customers.

9. Conclusion

Across 34 public documents and 15 commercial CTI providers, we identify recurring constraints that limit redistribution, automation, portability, and pricing predictability. Together, these patterns function as a *contractual firewall* that hinders cross-organizational coordination and disproportionately disadvantages SMEs, public-sector entities, and sector consortia.

The findings reveal a structural tension between commercial CTI licensing practices and European policy frameworks that mandate cooperative resilience and information sharing (European Union, 2022). Recent market consolidation, exemplified by Mastercard's acquisition of Recorded Future, suggests this concentration may intensify rather than dissipate.

The recommendations translate findings into concrete procurement requirements that improve portability, enable defensive sharing within trusted settings, and reduce lock-in risk. Future work should validate these patterns against negotiated enterprise terms and evaluate operational impact in incident response environments.

The current market structure creates a double failure in APT defense: (1) Economic gating excludes smaller defenders from essential intelligence, while (2) restrictive licensing prevents the collective ecosystem from compensating for this gap through sharing. Consequently, NIS2 mandates for collective resilience are rendered inoperable not by lack of will, but by commercial contract design.

Ethics declaration: This study analyses publicly available documents and does not involve human participants, personal data, or interventions. No ethical clearance was required. To support double-blind review, self-identifying references in the manuscript were removed where not essential to the argument.

Declaration of generative AI and AI-assisted technologies in the writing process: The author used AI-assisted tools to support language editing and LaTeX formatting, including improving clarity and grammar, reducing dyslexia-related spelling and ordering errors, and troubleshooting bibliography and layout issues. All AI-suggested changes were reviewed and approved by the author, who takes full responsibility for the final manuscript and any remaining errors.

Teemu.Hakkinen@laurea.fi
dominic.b.j.saari@jyu.fi

Abstract: This article examines the United Nations' efforts between 2021 and 2024 to promote the integrity of public information through the development of the Global Principles for Information Integrity. Responding to the growing threat of misinformation, disinformation, and hate speech, the study analyses how the UN sought to construct a non-binding, multilateral and multistakeholder response. Using qualitative textual analysis of UN reports, resolutions, and policy documents, the article traces the institutional process initiated by the Secretary-General's call for a global code of conduct and culminating in the adoption of the Global Principles in 2024. The findings highlight both the potential and the limitations of multilateral cooperation in a fragmented information environment marked by geopolitical rivalry and technological change. The study contributes to debates on global governance by illustrating how normative frameworks can be mobilized to address information integrity while navigating tensions between human rights, state interests, and platform governance.

Keywords: Information environment, Regulation, International cooperation, Multistakeholder, Integrity

1. Introduction

The increasing role of purposefully spread false, misleading, or inaccurate information online has become a global concern, and the United Nations (UN) is attempting to take a role to counter the phenomenon on multilateral basis. The UN has recognized disinformation as a threat and has also underscored the fundamental importance of freedom of information and access to accurate, reliable information as a human right. In 2021 its Secretary-General called for the end of "infodemic" challenging fact-based world by calling for a global code of conduct." (United Nations General Assembly, 2021a, 2)

The concept of "infodemic" refers to a particular kind of information environment in which the access of individuals to factual and timely information is weakened, with disinformation providing one element in the context. (Briand et al., 2023) The call for a global code of conduct in promoting the integrity of public information was a step onwards in countering disinformation at a global level, and after the Secretary-General started the building of a political momentum for such an effort, the work culminated in 2024 with the launch of Global Principles for Information Integrity.

Our research problem focuses on the integrity of public information as a topic for viable multilateral effort, i.e. how the UN processed the challenge. Our research question derived from the research problem is how the Global Principles were created and how the creation of the Global Principles reflected the state of multilateralism in attempting to set up a global response to the spreading of malign information.

The study contributes to the better understanding of multilateral dynamics in the UN decision-making in the context of how non-binding efforts can be made to guide member states and other stakeholders to establish common rules to regulate the current information environment.

2. Current Scholarly Discussion and the Case for Study

The UN is the leading multilateral organization in the world, but it has increasingly been under strain to draft relevant and effective responses to global challenges, highlighting weakening state of the UN and multilateralism as a broader phenomenon. (Weiss, 2016; Mingst, Karns and Lyon, 2022) As defined by John Ruggie (1992), multilateralism means cooperation between three states or more and is institutionalized in a particular context. Multilateralism relies on acceptance of common facts by states participating in the cooperation. If the sense of common facts is decreasing, this weakens the foundations under multilateral organizations (Martin, 2024).

Finding a commonly shared stance in mitigating the impact of malign and intended dissemination of information, especially hate speech, misinformation and disinformation continue to be a major global challenge (Ministry of Defence, 2024). The UN has started to work with countering malign information, and the

theme has gained attention especially since the COVID-19 pandemic, when the debates on health measures featured mass spreading of dis- or misinformation. (United Nations General Assembly, 2022b) Furthermore, the UN bodies can also act as forums for countering but also disseminating of disinformation as discursive activity (Taranenko, 2024).

In terms of regulatory responses, Christopher Marsden et al. suggest that effective governance requires a combination of legal frameworks and technological solutions, including the use of artificial intelligence (Marsden, Brown and Veale, 2020). This aligns with the findings of concerning the regulation of AI technologies to combat disinformation, emphasizing the need for democratic governments to adopt measures that enhance societal resilience and promote informed citizenry (Mega, 2023). Also, the UN work to regulate AI technology is noted (Fournier-Tombs, 2021). The UN's involvement in these regulatory discussions is meaningful, as it can facilitate international cooperation and the sharing of best practices among member states.

Often, discussion on global codes focuses on ethical practices, norms and standards in areas like environmental protection, corporate social responsibility, or migration (Armstrong, 2000; Vogel, 2008). In the field of finance, the UN has for decades promoted the use of global code to define rules and relations between transnational corporations and states (Sauvant, 2015). Similarly, the question of information-related threats link corporations with states. Promoting a particular kind of global code is a relevant perspective on the UN's role in addressing disinformation, given its mandate to maintain international peace and security and promote human rights while acknowledging in particular the role of the UN General Assembly in seeking consensus among the international community in a way that promotes both global democracy and involvement of civil society actors. (Thérien and Bélanger Dumontier, 2009) Furthermore, from the perspective of international relations theory such as constructivism, the global code relates to a question of whether there is and should be universal principles related to mitigating – and countering – disinformation, as a form of social norm (Björkdahl, 2002).

In this perspective, promoting a particular form of global code in the context of malign information could shed light on the UN's activities in setting up a global consensus and seeking to mobilize the member states of the UN, i.e. the global community at large to develop common measures to counter the phenomenon. Indeed, multilateral cooperation can take place in the context of regulating or shaping the information environment. However, the ways in which both the countering of malign information and in particular the focus on the protecting integrity of information can be combined should also shed light on the processes within the UN and how its role is viewed within the organization and outside of it, thus simultaneously engaging with the sense of multilateral organizations being under crisis (Schuette, 2024).

However, the promotion of global code has not been typical for UN activities. In fact, among the UN Meetings Coverage and Press Releases only 67 findings (press.un.org/en/sitesearch) can be found with the search term "global code" and in the UN Digital Library full text search between 1999 and 2024 only 592 records can be found to feature the search term, when applied in the system in June 2025. This highlights the relatively limited attention that the idea of global code has received in the UN's work so far.

3. Methodological Considerations

Our approach focuses on the exploration of the process in the UN to establish a global code on integrity of public information and recommendations and guidelines the UN provides for its member states and to other relevant stakeholders (e.g. private companies and non-governmental organizations) regarding information-related threats to such integrity. Sources for this article were extracted from the UN Digital Library with a full document search, with the help of keywords "'global code of conduct' AND "integrity of public information" (45 documents) as well as "counter disinformation" (156 documents) from the period 2021-2024. The search provided, among other types of documents, reports and resolutions of the Secretariat, the Security Council and the General Assembly.

Furthermore, the documents needed to feature commentary remarks on the state's role in countering disinformation or on the global code of conduct in the context of countering disinformation, and this served as the basis for close reading of documents. Documents were analyzed with contextualized, qualitative textual analysis in which the attention focused on the UN process to create the global code.

4. The Creation of the Global Code to Maintain Information Integrity

In the late 2010s member states of the UN accepted the view that various challenges impacting humankind, such as climate change and conflicts, were interconnected and thus requiring interconnected responses also

from the UN. As a result, in 2019 the UN adopted a Strategy and Plan of Action on Hate Speech. Instead of paying attention to disinformation in particular, the strategy focused on any kind of communication in speech that contains attacks or pejorative language in reference to individuals or groups (United Nations, 2019). Furthermore, effort by both states and companies to counter disinformation seemed occasionally to contradict with human rights, thus requiring new approaches with multistakeholder basis (United Nations General Assembly, 2021b). The Secretary-General António Guterres responded to increasingly challenging information environment with a report *Our Common Agenda* published in August 2021. In the report, the secretary-general called for the members of the international community to develop a "common, empirically backed consensus on the public good of fact, science and knowledge", as an effort to increase trust. Furthermore, he called for an institutional approach to disinformation by countering hate speech and online harassment and called for a "global code of conduct" that would promote integrity of public information. The underlying theme was the role of trust and mistrust towards both the technology and digital space, and a vision of a need to manage "our digital commons as a global public good". (United Nations General Assembly, 2021a, 17-18)

In his statement on the priorities for the year 2022, delivered in January 2022, Guterres highlighted the idea of multistakeholder approach to digital space and integrity of public information. He perceived the regulation of the digital world highly important but prone for risks, such as data misuse, misinformation and cybercrime, and linked the regulation in particular to different forms of business models taking place in the digital world. He also talked about the global code he had proposed as a multistakeholder effort linking governments, media companies and "regulators" together and saw it as a way to end both the "infodemic" and the war on science, while promoting integrity of public information both online and offline, and wanted the states to commit to the global code. (United Nations General Assembly, 2022a, 4-5)

4.1 Role of Hate Speech and Other Malign Information Activities

In late 2021, the General Assembly adopted a resolution (United Nations General Assembly, 2021c) in which it connected countering disinformation to the promotion and protection of human rights and fundamental freedoms, based on the United Nations Strategy and Plan of Action on Hate Speech in 2019.

In the resolution the General Assembly called states to "counter all forms of disinformation through policy measures, including education, capacity-building for prevention and resilience to disinformation, advocacy and awareness-raising", and the resolution both welcomed and took note concerning the Secretary-General's call for specific "global code for conduct that promotes integrity in public information". Furthermore, in the resolution the Assembly requested from the Secretary-General a specific report concerning the views of the UN member states, UN entities and other relevant stakeholders to provide ideas about best practices related to countering disinformation. (United Nations General Assembly, 2021c, 4) All in all, the resolution was a clear commitment by the General Assembly to place the issue of disinformation on the global agenda, and it paved the path for further work on the topic. The request for a report was a typical reaction and reflected the interest to emphasize the changing information – and thus operating – environment and next to broaden the discussion to cover all member states, UN entities and stakeholders otherwise relevant to the topic to mobilize international reaction.

From here the focus was on effort by the UN Department of Global Communications, led by the Under-Secretary-General for Global Communications. There the member states were supportive of the vision to establish the global code and reacted positively to an inclusive approach in its development. (United Nations, 2022, 7, 29) The idea of a global code was transformed into a document titled *Global Principles for Information Integrity*, highlighting the normative-aligned approach to mobilize both member states and other stakeholders to follow the guidance.

The Department of Global Communications in the General Assembly organized a global consultation round regarding the development of the Global Principles for Information Integrity. According to the report of the Secretary-General, the consultations round took a year to complete and involved several stakeholders, such as governments, civil society, the private sector, media and academia, and the process also involved dialogue with the Committee on Information as well as engagement through the system-wide Working Group on Information Integrity. After such a process, the official document was drafted. (United Nations General Assembly, 2024)

4.2 Content of the Global Principles

In 2023 the Secretary-General's office launched a policy brief aimed at developing what the global principles on information integrity could be. The brief also defined the concept of information integrity in the context of

threats. Indeed, the policy brief highlighted the digital information environment and the role of multiple different actors shaping the environment and linked the search for a global code to the upcoming 2024 event Summit for the Future as well as to work related specifically to information integrity in digital platforms. (United Nations, 2023, 5) The Global Principles were published in 2024 few months before the Summit for the Future and included five principles: societal trust and resilience; healthy incentives; public empowerment; independent, free and pluralistic media; and transparency and research and focus on providing recommendations to "all stakeholders regarding coordinated international action for safer and more humane information spaces that champion human rights, peaceful societies and a sustainable future." In practice this has meant a somewhat liberal approach to new technological environment, but in the framework of the UN focus on fostering the role of human rights: "Information integrity entails a pluralistic information space that champions human rights, peaceful societies and a sustainable future. It holds within it the promise of a digital age that fosters trust, knowledge and individual choice for all." (United Nations, 2024c) In the launching event of the Global Principles in June 2024, the Secretary-General described them as a starting point for solutions to counter misinformation, disinformation and hate speech in the context of proliferating role of generative artificial intelligence and strengthening democracy (United Nations, 2024b), but as the policy brief had already highlighted in 2023, such an effort related above all to the UN to set the aim in the international level and then invite member states to follow in the national level (United Nations, 2023).

Furthermore, Guterrez went on to describe the key audience for the Global Principles: the big tech companies to take responsibility over the impact of their products; advertisers and the PR industry regarding the monetization of harmful content; creatives of not wasting their talents to greenwash; PR agencies to better select their customers; media outlets to raise and enforce editorial standards; and governments to commit to free and plural media landscape (United Nations, 2024b). Nation-states, while in the focus of the UN system, simply were unable to shape the information environment to the extent necessary for the fulfilment of the UN secretary-general's vision.

4.3 Commitment to Multilateralism in the Context of Increasingly Maligned Information Environment

Understood in the context of multilateralism as a dialogue between governments' representatives to work out common approaches to common concerns (Schechter, 2011), the search for a global code reflected such an effort, a common approach to a common concern. In the context of the United Nations as the leading platform of multilateral cooperation and multilateralism suffering from a state of crisis (Newman, Thakur and Tirman, 2006), the issue of countering disinformation with promoting guidelines and encouraging states to act and to develop and share measures become particularly consequential. This applies particularly well to the chosen approach that goes beyond nation-states. Multistakeholder approach the UN promotes emphasizes an approach in which the member states are only one group of actors, among many others that shape, either intentionally or unintentionally, the global information environment.

In recent years multilateralism has experienced multiple forms of cooperation emerging, such as minilateral solutions particularly in the context of crises and crisis management (see Patrick, 2015) and discourse on multilateralism as a flexible and effectivity-based approach to international cooperation. (Bouchard, Peterson and Tocci, 2014; Karlsson-Vinkhuyzen and Dahl, 2022) Multistakeholder approach is part of a quest to foster more effective forms of cooperation by expanding the diversity of actors participating in global governance over secure information environment. Based on the process to create Global Principles for Information Integrity, the multilateral cooperation showed it can create principles with an aim to shape the complex information environment that surrounds both member states and the UN itself. However, as tends to be the case with the member states' relations with the United Nations, the question of whether principles will be applied to decision-making at a national level focuses on the level of commitment towards these principles. In the context of multilateralism, clear commitments at national level can be difficult to find (Fontaine-Skronski, Thool and Eschborn, 2023, 2) and a similar idea may well apply to the question of how to protect and strengthen the integrity of public information. Indeed, already in 2024, some evidence emerged. In the Summit of the Future, held in September 2024, information security was also well present. The Summit was a high-level event designed to bring world leaders together and try to find an international consensus on a better present and future and make commitments to jointly agreed goals. The Summit originated from *Our Common Agenda* report of the Secretary-General and the states participating in the event adopted a document titled *Pact for the Future*, highlighting various commitments the states had made in the Summit. Some commitments were made under the banner of information integrity, and in the context of threats posed by misinformation and disinformation. There the commitments included digital media and information literacy

measures to strengthen resilience towards malign information and measures related to dissemination of independent, fact-based and accessible information. (United Nations, 2024a, 45)

4.4 Discussion: Are the Global Principles Enough?

Social media and digital communication tools are now firmly embedded in state strategies to influence audiences and challenge adversaries. This has not gone unnoticed by the world's major powers, each with a rich history of employing psychological operations, some of which have been controversial in their methods. For instance, the United States recognizes information as an instrument of national power (Department of Defense, 2013). China, meanwhile, has expressed its intention to contest what it sees as Western dominance over global discourse (Zhao, 2016).

This renewed great power competition is increasingly unfolding in the digital domain. Russia, for example, has been linked to efforts to interfere in foreign elections and spread disinformation across global platforms. (Maréchal, 2017) China has intensified its influence campaigns, aiming to challenge U.S. influence in the international information environment. One of the largest known disinformation networks, referred to as Spamouflage, has been attributed to China. According to Meta, the network included more than 7,000 Facebook accounts, 954 pages, 15 groups, and 15 Instagram accounts. These accounts operated across at least 50 different platforms and forums, primarily aiming to promote pro-China narratives and to discredit the United States and other Western countries. (Meta, 2023)

Influence operations, once primarily associated with authoritarian regimes, are now also used—albeit differently and often on a more limited scale—by democratic states. Beyond the major powers, other states have also been implicated in information operations. France, for instance, has been accused of using disinformation tactics, including social media trolls and bots, to counter Russian influence efforts in Africa. (Gleicher and Agranovich, 2020)

While Russia, China and other authoritarian states have sought to insulate their information environments as a form of defense (Bendix, 2026), smaller states often lack the capacity to do so. Instead, they remain dependent on global platforms—such as Western social media or Chinese infrastructure—not out of strategic choice, but due to practical necessity.

As members of the UN Security Council face increasing competition in the global information space, it is fair to question whether the major powers are genuinely committed to supporting the Global Principles or if their differing priorities will continue to drive their actions. The behaviour of key actors often reflects a more self-interested and pragmatic approach.

In this context, smaller states increasingly find themselves relying on multinational alliances—such as the European Union or even the UN itself—to amplify their voices and defend their interests. Initiatives like the EU's Digital Services Act (DSA), which aims to regulate online platforms and increase transparency, offer one example of how collective action can strengthen digital resilience. (Heldt, 2022) Yet this dynamic—where larger powers dominate the information space—not only undermines the spirit of a genuine multi-stakeholder approach but also risks reinforcing a 'might makes right' logic, often at the expense of the sovereignty of smaller states.

The success of new UN agreements remains uncertain. While the Global Principles offer a valuable starting point, they may not be enough to address the challenges posed by geopolitical tensions, rapid technological disruption, and differing conceptual approaches to information. Ultimately, the effectiveness of these principles will depend on whether sustained cooperation and political commitment can be achieved—an outcome that remains uncertain in today's volatile global climate.

5. Conclusion

In this study we asked how the Global Principles were created and how the creation of the Global Principles reflected the state of multilateralism in attempting to create a global response to the spreading of malign information.

Our study shows that the UN took an actor-bound approach in creating Global Principles by first acknowledging the existence of information threats and then, together with the relevant UN entities, worked both to consult member states and other stakeholders to find a common response to the challenges malign information was showing. The process, after the first call for global code took place in 2022, took two more years to come up with a document outlining the principles for the Summit for the Future to consider and help

commit states to the principles, thus showing gradual multilateral process to study the challenge and the defined suitable responses.

The global environment increasingly highlights the role of great power rivalry. In this context, reaching international consensus on issues may be increasingly difficult to achieve. Nevertheless, to have some level of regulation among great powers and creating rules and norms of states and non-state actors to follow should be done with enough mobilization. In this evolving situation it is increasingly important to link efforts to counter the spreading of malign information with human rights law and principles. Here the future promotion of Global Principles and mobilization of states to implement the principles becomes important and could bring hope to aim next for stronger form of international regulation.

Ethics declaration: Ethical clearance was not required for the research.

AI declaration: Three AI-based research tools were utilized in the reporting phase: Jenni.ai (https://jenni.ai/) for text editing the first draft of the manuscript and Scite.ai (https://scite.ai) to help in the drafting the literature review, although in the further revision rounds their impact became almost non-existent, and Microsoft 356 Copilot to create a draft abstract.

The University of Maryland's Cyber Events Database 2.0: A Systematic Framework for Analyzing Global Cyber Threats

Charles Harry, Devin Entrikin and William Lucyshyn
The Center for Governance of Technology and Systems (GoTech) at the University of Maryland's School of Public Policy, College Park, USA

charry@umd.edu
dentrik@umd.edu
lucyshyn@umd.edu

Abstract: Cyberattacks are increasing in scale, scope, and impact, yet systematic, accessible data on these events remain fragmented, narrowly scoped, or methodologically opaque. Existing cyber incident datasets often focus on specific threat types or high-profile cases, are proprietary, or lack transparent coding rules, limiting comparative analysis and cumulative research. This paper introduces the Cyber Events Database 2.0 (CEDB 2.0), a publicly sourced, event-level repository of global cyber incidents from 2014 onward designed to support reproducible research and strategic cybersecurity analysis. The CEDB 2.0 employs a mixed-methods data collection approach that combines automated web scraping with multilingual, near–real-time news monitoring, integrating the Global Database of Events, Language, and Tone (GDELT) Project beginning in 2025. As of February 2026, the database contains 16,382 coded cyber events across 175 countries and 1,431 distinct threat actors. Each event is classified using a theory-informed taxonomy capturing actor type, motive, target sector, affected country, and observable effects. By enabling cross-sectional and longitudinal analysis at scale, the CEDB allows researchers to move beyond anecdotal case studies toward systematic, evidence-based assessment of state and non-state cyber behavior. The paper details the database's methodology, structure, applications, limitations, and future development.

Keywords: Cybersecurity, Cyber operations, Structured event data, Threat landscape, Data-driven analysis, Strategic decision-making

1. Introduction

Cyberattacks are growing in number and impact, carried out by various actors with different motives, targeting multiple industries and causing effects from data breaches to operational disruptions. These incidents, including the 2021 ransomware attack on Colonial Pipeline that interrupted fuel supplies along the eastern U.S. (Easterly, 2023), the 2020 SolarWinds breach attributed to Russian operatives that compromised numerous systems (GAO, 2021), and recent attacks on water utilities linked to pro-Russian and Iranian groups (ODNI, 2024), all represent cyber events significant to academic research. Less severe incidents, such as attacks on schools (Kennedy, 2024), small contractors (Rogers, 2020), and software vendors (JD Supra, 2023), are less frequently discussed, leading much of the analysis to be based on a small data sample subject to sampling bias. Information regarding the individuals or groups responsible, their intentions, the affected sectors, and the actual consequences is typically scattered across news reports, specialized private intelligence agencies, periodic statements by businesses and governments, or subscription-based commercial databases. While some open-source data repositories of cyber events exist, they often contain information that remains fragmented, narrowly scoped, or methodologically opaque.

To address these shortcomings, the Center for the Governance of Technology and Systems (GoTech) has expanded on initial work in conjunction with the Center for International and Security Studies at Maryland (CISSM) to develop and launch a revised Cyber Events Database (CEDB 2.0). CEDB 2.0 integrates publicly accessible news articles by referencing identified cyber-relevant news and trade publications, as well as the Global Database of Events, Language, and Tone (GDELT) Project's Web News NGrams 3.0 (2021) and Article List datasets. The CEDB now offers comprehensive global coverage through real-time monitoring of news sources in over 65 languages, ensuring broader, more timely access to information.

This article outlines the purpose, methodology, structure, and uses of CEDB 2.0. It reviews the relevant literature, explains methods, describes database fields, and covers use cases, limitations, and future prospects. By highlighting cyber events, the CEDB 2.0 helps reassess key issues, including threat locations, motives, patterns, impacts, and responsible actors.

2. Literature Review

Cyber events vary across multiple critical dimensions, including threat actor type and motivation, targeted industry, geographic scope, and the nature and severity of observable effects. Despite this heterogeneity, cyber event reporting remains inconsistent and difficult to standardize. Many existing data collection initiatives fail to

meet foundational criteria of exhaustiveness, exclusivity, and consistency, limiting their suitability for comparative and theory-driven analysis (Harry & Gallagher, 2018). Others focus on specific threat categories or technical artifacts, struggle to capture evolving attack vectors, rely on incomplete or outdated records, or lack adequate coverage of multi-stage and multi-actor campaigns (Cremer et al., 2022; Mvula et al., 2023; Goldschmidt & Chudá, 2024). As a result, much of the empirical work on cyber war and security relies on qualitative methods over quantitative large-N analysis (Kong, Kim, and Lim, 2019) (Buchanan, 2020), with some notable exceptions (Valeriano, Jensen, and Maness, 2018) (Kostyuk & Zhukov, 2017). Collectively, these limitations undermine consistent event classification, obscure meaningful variation across incidents, and introduce selection bias, which complicates inference and policy-relevant analysis.

We reviewed 13 datasets, often cited in academic and professional publications, that are most closely related to the CEDB 2.0. The datasets are broadly reviewed within four distinct groups based on their observed focus, completeness, audience, and description. The first group of cyber incident datasets prioritizes state-linked activity or high-impact events rather than the broader universe of cyber threats. For example, the Center for Strategic and International Studies (CSIS) Significant Cyber Incidents timeline documents notable cyberattacks since 2006, emphasizing state-sponsored operations, espionage, and incidents with estimated losses exceeding $1 million, particularly those affecting government and defense targets (CSIS, n.d.). Similarly, the Council on Foreign Relations (CFR) Cyber Operations Tracker catalogs state-attributed cyber operations with an explicit focus on interstate dynamics and strategic competition (CFR, n.d.).

Both resources provide valuable descriptive context but are not designed as taxonomic or event-level datasets. Events are coded narratively rather than through a standardized, multi-dimensional classification scheme, and inclusion criteria privilege strategic salience over systematic coverage. As a result, these datasets are ill-suited for large-N comparative analysis, replication, or longitudinal assessment of variation in actor behavior, targeting patterns, and effects across different types of cyber activity.

A second group focuses on intrusion detection and specific threats. This includes the Canadian Institute for Cybersecurity (CIC) datasets, such as CIC-IDS2017, which provide network flow data for intrusion detection and machine learning applications that simulate specific attack vectors (e.g., DDoS or malware). However, they lack real-world incident narratives or longitudinal trends (Sharafaldin et al., 2018). While invaluable for detection and model training, these datasets capture technical artifacts rather than socially and politically situated cyber events with identifiable victims and consequences.

A third category of datasets monitors broad cyber incidents rather than specific subtypes. The European Repository of Cyber Incidents (EuRepoC) offers a comprehensive global dataset encompassing over 3,400 politically or security-relevant cyber operations from 2000 to 2024, featuring 60 variables pertaining to initiators, targets, and intensity. Similarly, the Dyadic Cyber Incident and Campaign Dataset (DCID) focuses on campaigns and incidents associated with interstate conflicts. Although these datasets are methodologically robust, their emphasis on actions by major state actors may underrepresent non-state proxies, such as criminal entities and hacktivists. Additionally, their primary focus on interstate conflict constrains their capacity to document cyber operations occurring within intrastate conflicts.

A fourth group comprises specialized, community-driven, or technically focused repositories, each centered on specific attack categories. For example, Ransomware.live automates the scanning of ransomware groups' data leak sites and other sources (Ransomware.live, n.d.; Poireault, 2024). Likewise, Ransomware monitors cryptocurrency payments sent to wallets associated with known ransomware activity (Ransomwhere, n.d.; Cable et al., 2024). The U.S. Department of Health and Human Services Office for Civil Rights (HHS OCR) gathers reports of HIPAA-covered breaches that impact 500 or more people in the healthcare field (HHS, 2023; Alder, 2025). Cloudflare observes major Internet disruptions, including DDoS campaigns or state-mandated shutdowns (Cloudflare Radar, n.d.; Azevedo, 2023). Shadowserver offers global threat telemetry (Shadowserver, n.d.; Kijewski, 2021) while the “World’s Biggest Data Breaches & Hacks” compiles cyber event information into a timeline with source links (Information is Beautiful, n.d.). These tools tend to have a narrow focus, ambiguous event classifications, technical orientations, or limit themselves to certain types of incidents.

Collectively, these four categories of cyber event data repositories demonstrate both the advancements achieved and the ongoing challenges in documenting cyber activity. State-centric timelines prioritize strategic significance over comprehensive coverage and intrusion detection datasets focus on technical indicators but often lack contextual and impact information. Dyadic and interstate repositories limit analysis to specific participants and conflict patterns and specialized or community-driven platforms offer detailed insights into threat vectors. Consequently, no single dataset currently provides thorough, event-level data that is sufficiently

broad, methodologically transparent, and systematically organized for comparative and longitudinal research across actors, sectors, and regions. These gaps highlight the necessity for a unified, publicly accessible repository of cyber events that synthesizes diverse sources, employs a consistent classification scheme, and records the tangible effects of cyber operations, objectives addressed by the CEDB 2.0.

3. Methodology

The CEDB 2.0 is designed to provide a systematic, event-level record of global cyber activity that supports comparative, longitudinal, and policy-relevant analysis. Building on earlier efforts to document cyber incidents using open-source reporting, the CEDB 2.0 applies explicit inclusion criteria, a structured taxonomy, and a hybrid data-collection approach that combines automation with human validation. This section outlines the database's event definition, data collection pipeline, and validation process, highlighting methodological choices intended to mitigate selection bias and improve global coverage. The first source stream relies on automated web scraping of a curated and regularly updated watchlist of open-source outlets known for timely reporting on cyber incidents, including specialized cybersecurity blogs, major news organizations, public feeds, leak sites, and paste sites. Prior to 2025, this Python-based scraping pipeline served as the primary mechanism for identifying candidate events.

The site-specific scraper collects cyber-related articles via RSS feeds (using feedparser, rapidfuzz, dateutil.parser, etc.), then filters entries by date, keyword match, and deduplication. For each retained entry, it records the RSS publication timestamp (reported_date), the article link (source_url), and the RSS summary text (description), as well as the RSS title. Execution timing is captured in log files via a local timestamp. Where possible, preliminary indicators of threat actor type and apparent motivation are inferred heuristically from textual context, though these provisional labels are always subject to subsequent human review.

Beginning in January 2025, the data collection was expanded to include the GDELT Project's Web News NGrams 3.0 (2021) and Article List datasets. GDELT's near-real-time monitoring of broadcast, print, and online media in over 65 languages across more than 100,000 sources. This dramatically increases both temporal recency and geographic breadth of coverage, particularly for incidents reported outside English-language specialist outlets. As an example, the U.S. share of recorded cyber events declined from 48.8% to 36.9% when comparing the 2014–2024 dataset, compiled using the original collection method, to records from 2025 onward, when GDELT-based identification was incorporated. The change likely reflects improved global coverage rather than a substantive shift in cyber activity. Events ingested via GDELT are subjected to the same definitional criteria and manual validation workflow as traditionally scraped incidents; only the upstream acquisition mechanism differs. This methodological shift is explicitly flagged in the dataset schema to enable temporal-comparability analyses.

Harvested records are aggregated daily, deduplicated by URL and semantic similarity, and appended to two intermediary comma-separated values (CSV) files, one containing raw open-web scrapes and a second reserved for post-2025 additions from GDELT-sourced articles. Importantly, the algorithm's sole function is to collect potentially relevant material, which is then reviewed by one of the researchers.

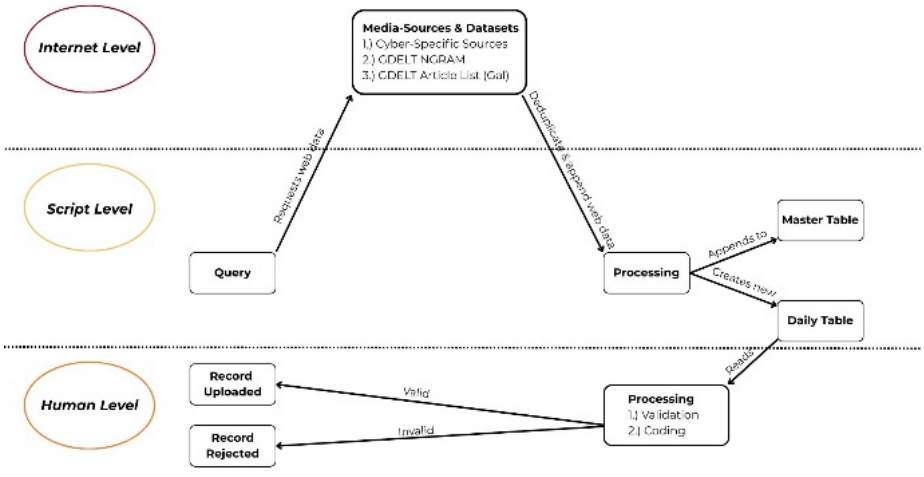

Figure 1: Data Collection and Coding Process

Following daily aggregation, trained researchers restrict inclusion to cyber events that meet two necessary conditions: (1) the operation must have produced a discernible real-world effect, and (2) there must be an identifiable target victim. Events that lack an observable impact against an entity, such as unsuccessful intrusions, or vulnerability disclosures without exploitation are systematically excluded. Each record is linked to at least one publicly accessible or archived primary source containing sufficient narrative detail to support independent verification and consistent coding.

Each cyber event record consists of 45 standardized fields that document what happened, who was affected, and how. The event date reflects the best available information on when the intrusion or effect occurred, while the reported date is the publication date of the cited source URL. Each record includes a specific victim organization (or individual) and its corresponding two-digit NAICS industry code when available. Threat actors fall into one of the following categories: criminal, nation-state, hacktivist, hobbyist, terrorist, or undetermined. Events are categorized by primary effect as exploitive, disruptive, or mixed (both exploitive and disruptive effects). Subtypes specify the nature of an event based on the part of the target organization's IT infrastructure that was most seriously impacted. These include disruptive subtypes such as data attacks, message manipulation, external or internal denial-of-service, physical attacks, or specific forms of exploitation against application servers, end hosts, network infrastructure, sensors, and/or data in transit. Beginning with 2025 data, disruptive and mixed events include severity coding for magnitude (extent of disruption), duration (length of disruption), and scope (systems or assets affected). Exploitive and mixed events record compromised data by category, which includes intellectual property, organizational data, and customer or client data, using quantitative detail whenever possible. Motive is coded as financial, political or industrial espionage, sabotage, protest, reputation, personal attack, or undetermined based on evidential inference. Additional fields capture victim and actor countries using standardized naming and ISO3, binary variables for organization and alliance membership, a concise factual description, and a verifiable source link. Finally, for cyber events targeting the United States, records also capture the state and county where the organization operates, if available.

This process serves three primary objectives:

- Confirmatory validation that the candidate event has both an attributable victim and observable effect;
- Consistent assignment of core taxonomic attributes; and
- Precise classification of affected industry and granular end effects according to the structured impact taxonomy

Processed and validated records are consolidated, deduplicated across both ingestion streams, and released in monthly cumulative updates accompanied by schema documentation and a change log that highlights any coding adjustments. The resulting dataset thus offers scholars a transparent, reproducible, and longitudinally consistent resource for quantitative (and qualitative) analysis of cyber conflict dynamics (Harry et al., 2025).

4. Results

As of January 2026, the database contains 16,382 cyber events across 175 countries involving 1,431 unique threat actors. The average number of events per month is 112, and the yearly average is 1,239 (2014-2025). When we break the data down by types of effects, exploitive events are the most common, driven largely by criminal actors seeking financial gain through data theft and extortion. Mixed-effect attacks, such as ransomware that combines data theft and encryption, saw a spike in 2022 and 2023. However, there has been an observed shift in threat behavior in recent years as more criminal actors use data theft-only extortion methods (Symantec & Carbon Black, 2026). Interestingly, there is a notable spike in disruptive attacks in 2022, which aligns with heightened hacktivist and nation-state activity following Russia's invasion of Ukraine.

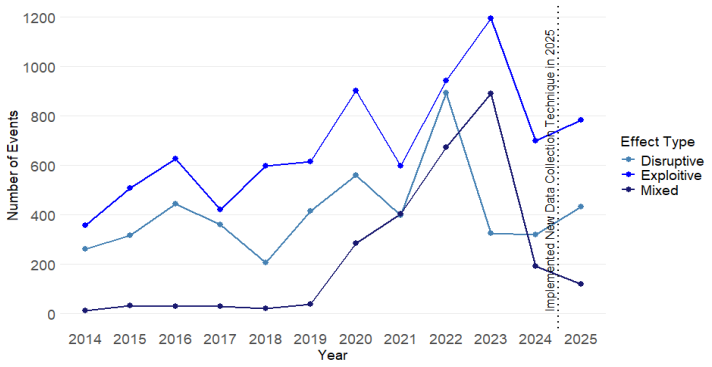

Figure 2: Cyber Events by Effect Type - All Records (2014-2025)

Figure 3 shows that criminals, driven by financial gain, are, by far, the most prolific threat actor, accounting for 74.5% of events tracked in the CEDB 2.0, while hacktivist groups, motivated by ideological or political alignments, are the second most active (with a 13.2% share) for the period 2014-2025. Russia's invasion of Ukraine led to a spike in hacktivist activity and continues to motivate groups such as Russian-aligned NoName057(16) efforts to disrupt NATO-allied countries that support Ukraine's defense. Additionally, Ukraine relied heavily on hacktivist groups such as the IT Army of Ukraine for both offensive and defensive cyber operations in the early days of the war.

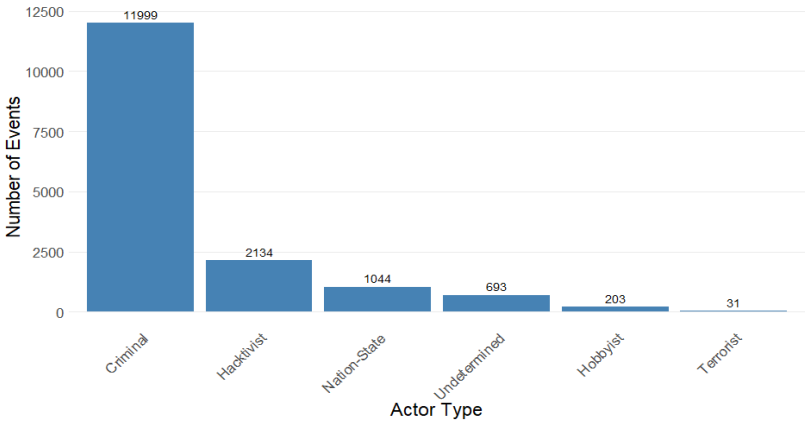

Figure 3: Cyber Events by Actor Type (2014-2025)

Figure 4 spotlights that cyber events are most frequently concentrated in public-facing and data-intensive sectors. Public administration and health care account for the largest shares, reflecting both their high operational dependence on IT systems and relatively strong disclosure requirements. Information, finance, and education also appear prominently, suggesting that sectors managing sensitive data or providing essential services face sustained exposure to cyber activity, while more asset-heavy sectors such as manufacturing and transportation experience comparatively fewer reported events.

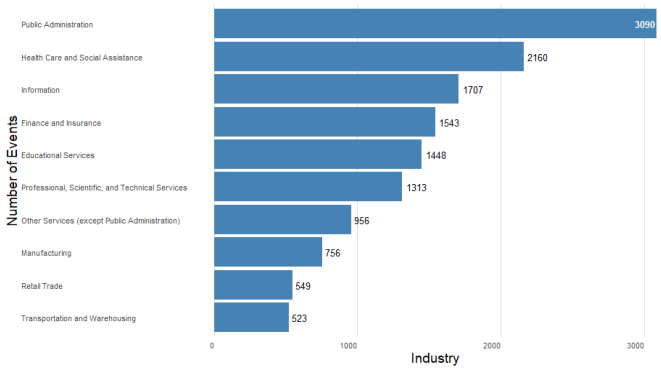

Figure 4: Top 10 Most Targeted Industries (2014-2025)

Figure 5 shows a strong concentration of recorded cyber events in a small number of countries, with the United States accounting for a 47.6% of total events. While reporting volume, disclosure regimes, and media coverage clearly play a significant role in shaping the geographic distribution of events in the dataset, the United States is also a very attractive target considering its robust industrial activity, economy, and geopolitical significance. The remaining nations are all relatively large G20 economies, and Ukraine is included due to its status as a war zone.

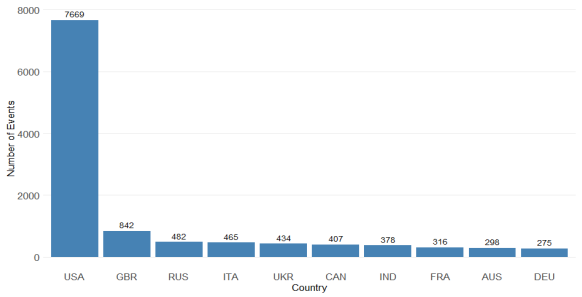

Figure 5: Top 10 Most Targeted Countries (2014-2025)

Finally, the threat actor distribution suggests that *observed* cyber activity is highly concentrated among a small number of persistent and operationally active groups, including criminal, hacktivist, and nation-state actors. cl0p has been the most active criminal group, reflecting both their high operational tempo and relatively robust resourcing, as well as the fact that their activities are more likely to be publicly reported and attributed. The appearance of advanced persistent threat (APT) groups among the top ten actors, such as North Korea's Third Surveillance Bureau and Russia's GRU Main Special Center for Special Technologies (Unit 74455), highlights the sustained visibility of certain state-linked campaigns within the dataset. For instance, the presence of Russia's GRU Unit 74455 reflects its association with highly visible, disruptive campaigns, most notably NotPetya, one of the most damaging cyber operations on record, which generated widespread collateral effects (U.S. Department of Justice). By contrast, the Third Surveillance Bureau-linked activity associated with North Korea blends traditional espionage with overt financial operations such as cryptocurrency theft and revenue-generating intrusions, which are more likely to surface in open-source reporting.

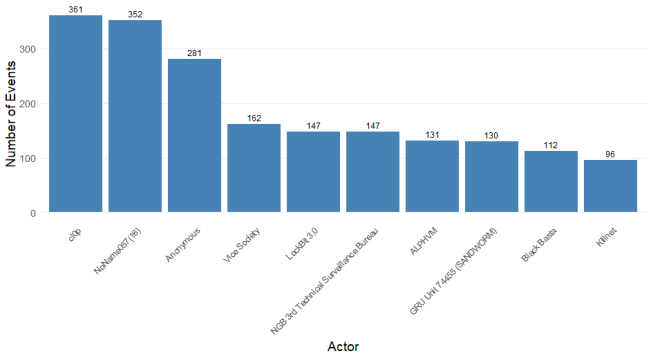

Figure 6: Top 10 Threat Actors (2014-2025)

5. Discussion

The CEDB 2.0 significantly enhances the analytical landscape for cybersecurity research by enabling scholars to address previously challenging questions due to data limitations. By providing structured data on actor types (e.g., nation-state, criminal, hacktivist), motives (e.g., espionage, sabotage, financial gain), and geopolitical affiliations through binary indicators for international organizations like NATO, or the EU, researchers can empirically test hypotheses about the nature, origins, and escalation of threats. Categorizing and contextualizing cyber events positions CEDB 2.0 as a valuable resource for industry and country-level threat landscapes, longitudinal trend analysis, effect and severity analysis, among other uses, all in service of knowledge generation and strategic decision-making.

Moreover, the CEDB 2.0 has also proven to be a vital resource for generating analytical insights and supporting evidence-based cybersecurity policymaking. In a comprehensive study, World Bank researchers integrated the CEDB with advanced artificial intelligence tools and then analyzed millions of cybersecurity-related articles. They

created a robust dataset covering approximately 190 countries and 21 industries, documenting over 30,000 publicly disclosed cyber incidents from 2014 to 2023. This enabled the identification of critical trends, such as a 21% average annual growth rate in global cyber incidents, with upper-middle-income countries experiencing a 37% surge. By linking incident frequency to cybersecurity commitments, the database provided policymakers with actionable insights. These findings highlighted the need for tailored policies, such as enhanced cybersecurity investments and awareness programs, particularly in developing nations, to mitigate cyber risks and foster sustainable digital development (Vergara Cobos & Cakir, 2024).

Another example of its utility is the European Securities and Markets Authority (ESMA) inclusion of CEDB 2.0's data in their Semi-annual Trends, Risk and Vulnerability (TRV) report (ESMA, 2024), incorporating the data into the TRV Statistical Annex (Chart A.131) to illustrate the rising global trend of cyber incidents in finance. The database's standardized information on threat actors, motives, targets, and impacts enabled ESMA to rank Infrastructure and Services at an elevated risk level, projecting ongoing cyber and operational vulnerabilities. The database's insights helped contextualize specific incidents, such as the CrowdStrike software update outage and Russia's cyberattacks against Ukraine, impacting EU entities. (ESMA, 2024).

The CEDB has been widely adopted in both analytical and policy initiatives, demonstrating its value in academia and beyond. It supports projects like CyberIR@MIT and Bamboo Weekly (2024) in compiling and analyzing cyber event data. It informs financial risk assessments by central banks such as the Bank of Japan (2023) and the European Central Bank (2022), among several other organizations.

Future iterations of the dataset will focus on achieving greater fidelity of event-level information. Planned enhancements include the integration of six-digit NAICS industry classifications, expanded organizational attributes, and the systematic backfilling of severity indicators across historical records. Increasing the granularity of these variables will enable more precise sectoral analysis and facilitate deeper empirical research on how cyber operations vary across industries and organizational types. Future development will also explore mechanisms for identifying and tracking cyber events involving artificial intelligence–enabled tools and techniques as these capabilities change the cyber threat landscape.

5.1 Limitations

Like most open-source cyber incident datasets, the Cyber Events Database relies on publicly available reporting, including news coverage, regulatory disclosures, and statements from affected organizations. As a result, events that are undisclosed, classified, intentionally concealed, or that occur in environments with limited media freedom are likely underrepresented. Coverage also varies across regions and sectors due to differences in legal reporting requirements, journalistic capacity, and organizational transparency, resulting in uneven geographic and industry representation. In addition, while the database increasingly incorporates multilingual sources, challenges remain in processing non-English reporting at scale and ensuring real-time accuracy as details about cyber events often evolve after initial disclosure.

6. Conclusion

The CEDB 2.0 provides a publicly accessible repository of structured, event-level data on global cyber incidents, enabling researchers, policymakers, and practitioners to analyze trends, assess risk, and support evidence-based decision-making. The integration of multilingual, near–real-time news monitoring through GDELT in 2025 expanded the database's geographic coverage, enabled timelier updates, and strengthened its utility for cross-sectional and longitudinal analysis across threat actors, motives, industries, and regions. With more than 16,382 recorded events spanning 2014 through 2025, CEDB 2.0 facilitates systematic case selection and comparative analysis, including fine-grained filtering of incident types, motivations, and actor characteristics.

Looking ahead, the CEDB 2.0 will support a comprehensive empirical analysis of cyber activity associated with actors linked to the Russian Federation. Leveraging the database's event-level coding of actor type, motive, sector, and observable effects, this research will build on previous research to examine patterns in targeting behavior, operational methods, and outcomes across time and geographic contexts in relation to the ongoing war in Ukraine (Lilly & Cheravitch, 2020) (Microsoft, 2022). The dataset's structure enables systematic comparison of state-attributed espionage and disruptive operations with hacktivist and proxy-based campaigns, including ransomware and data theft, allowing assessment of convergence, divergence, and potential coordination.

The CEDB 2.0 supports empirical research on cyber conflict, improves situational awareness for organizations assessing sector-specific risks, and informs policy discussions on infrastructure resilience, deterrence, and

international cooperation. In doing so, the dataset helps shift discussions of cyber operations from anecdotal observations toward transparent, evidence-based analysis.

Ethics Statement: This research did not require ethical clearance since we rely exclusively on publicly available media reporting.

AI Declaration: AI tools were used to assist with language editing, translation of non-English source material, and clarity checks. All substantive analysis, interpretation, and final content decisions were made by the authors.

Abstract: The technical feasibility of crafting polyglot files, objects valid under multiple file formats, has been repeatedly demonstrated in various contexts, including the DICOM medical imaging standard. While prior work has established that DICOM polyglots are technically constructible, a significant operational gap exists between this known vulnerability and the preparedness of healthcare organizations to detect and mitigate such data-centric threats. This paper addresses this critical oversight by shifting the focus from how to construct DICOM polyglots to why they pose an unmitigated, systemic risk in clinical workflows. We argue that this operational gap stems from three primary issues: non-uniform inspection across heterogeneous security tools, misplaced trust in the structural compliance of medical data, and insufficient threat modelling for automated pipelines. Our feasibility analysis, using a controlled DICOM/Portable Executable (PE) polyglot, demonstrates that mainstream security tools exhibit substantial inconsistencies in detection, with different systems interpreting the same object according to varying, often shallow, parsing assumptions. This non-uniform inspection allows the polyglot to remain stealthy and polyglot. To provide a structured framework for analyzing and mitigating this threat, we introduce the S.P.I.C.Y. framework, defined by five operational characteristics: Stealthy, Polyglot, Infiltrative, Cascading, and Yield. S.P.I.C.Y. helps practitioners measure the operational impact of malicious data artifacts that propagate through trusted, automated workflows, such as Picture Archiving and Communication Systems (PACS) and Vendor Neutral Archives (VNAs). The Infiltrative and Cascading characteristics highlight how an object, once past initial inspection, maintains its dual functionality across multiple automated processes. Finally, we redefine Yield to include not just execution, but the operational value gained from persistence within trusted infrastructure. By applying the S.P.I.C.Y. framework, organizations can move beyond traditional security models and strategically address the critical blind spots created by operational complexity and the assumed trust placed in medical data standards.

Keywords: DICOM, Polyglot, Healthcare, Cybersecurity, S.P.I.C.Y., Operational gap, Automated pipeline

1. Introduction: The Dual Nature of Medical Data

Cybersecurity increasingly exploits ambiguities in trusted digital systems. As automation and usability take their toll, these trust boundaries begin to waver. Antiquated standards and automation create assumed trust boundaries as files are pushed through increasingly complex pipelines. Adversarial techniques increasingly take advantage of these structural ambiguities. Polyglots take advantage of these ambiguities. Polyglots are defined as a single byte sequence that is syntactically valid under multiple file format specifications and can be meaningfully processed by more than one independent parser. Prior research has identified numerous file formats capable of supporting polyglot constructions, such as PDF, Jpeg, ZIP and many others. (Albertini, 2015). Through polyglot techniques, it becomes possible to construct objects that expose weaknesses in assumptions about file structure and interpretation.

The DICOM standard is a foundational fixture in medical imaging. Security validation has not matured alongside security threats, leaving a gap in operational security. The DICOM Part 10 file structure is pushed through automated pipelines repeatedly. Practitioners face attack surface gaps formed from inconsistent detection and overlapping weakened trust boundaries. The DICOM file structure has led researchers to discover a critical example of a threat that develops from such ambiguity (Ortiz, 2019). Polyglot-capable conditions resulting from the asymmetry between extensibility in the DICOM standard and validation gaps in detection tools have created an attack vector that relies on opaque file structures and avoids most inspection.

Current frameworks do not provide a means to assess the risk of data-centric threats and their potential operational blast radius. While previous research has demonstrated feasibility, the operational impact and implications for automated medical systems remain insufficiently explored (Ortiz, 2019). We propose the S.P.I.C.Y. framework to assist practitioners in analysing these polyglot threats and expose defensive gaps created by operational assumptions and complexity. Traditional threat modelling frameworks, such as the Cyber Kill Chain and MITRE ATT&CK, focus on specific vulnerabilities or attacker techniques and tactics

(Hutchins et al., 2011; Strom et al., 2018). S.P.I.C.Y. instead measures the operational impact of malicious data artifacts that propagate through automated workflows and trusted pipelines.

2. Theoretical Framework: S.P.I.C.Y. and the Polyglot Taxonomy

2.1 S.P.I.C.Y. Framework Introduction

Polyglots as a threat form an ambiguous, even hard to quantify, gap in the standard assessments for exploits and vulnerabilities. Traditional threat models evaluate threats through software flaws or execution paths. Polyglots function as a result of data interpretation and structural format ambiguity. To help define and describe such behavior this paper introduces the S.P.I.C.Y. framework, which is defined through five operational characteristics: Stealthy, Polyglot, Infiltrative, Cascading, Yield.

Stealthy is used to understand how polyglots are positioned to abuse ambiguous structural elements of formats, standards, and specifications to evade consistent detection. The ability of a polyglot to leverage these ambiguities depends on the gap in analysis and inconsistency of security tools in their respective environments (Albertini, 2015). Stealthy asks: How consistently is the polyglot object recognized across the different layers of inspection in a workflow?

Polyglot emphasizes the object's ability to be valid under different interpretations and contexts. Simultaneously able to conform to multiple formats and remain valid. As an example, different DICOM polyglots conform to distinct dual states (Ortiz, 2019). Polyglot asks: How many separate unique file formats can the object conform to while retaining core functionality?

Infiltrative describes the object's ability to pass different layers of ingestion without raising alarms. DICOM polyglots are accepted by typical ingestion services like DICOMweb STOW and then flow into PACS systems (Pianykh, 2012; Kahn et al., 2016). Infiltrative asks: Can this object successfully be ingested at point of entry without failing to validation or other inspection tools?

Cascading alludes to the polyglot's ability to successfully retain its multifaceted functionality despite moving through different transformations and systems as it moves through workflows. DICOM files move through PACS, VNAs, and AI workflows. The ability of polyglot to contain data within private elements and preamble show these structures may endure (Mirsky et al., 2019). Cascading asks: does the polyglot retain functionality through these transfers and transformations applied by the pipeline?

Yield identifies the operation value that is achieved once a structurally stable polyglot enters and persists in the workflow. Execution is not the only valid operational goal. The presence of executable code embedded in trusted medical data allows for a form of persistent, deferred activation. Downstream handling and reuse of images allow for exposure and embedding of code further than reliant on immediately executable code could achieve.

2.2 Polyglot Taxonomy

We have defined the taxonomy of polyglots into three sets of definable characterizations-structural, semantic, and operational - to provide a systematic framework for understanding how polyglot files are constructed, evade defensive controls, and are weaponized in operational workflows. This taxonomy is intended to address the concerns of a distinct but overlapping audience involved in the security and governance of data systems: the structural taxonomy is relevant to software developers, standard authors, and tool builders, allowing for an understanding of byte-level construction that remains syntactically valid under multiple formats; the semantic taxonomy is directly applicable to security engineers, detection vendors, or incident responders and focuses on inspection and validation mechanisms that fail when polyglots are encountered in practice; and the operational taxonomy is directed toward system architects, risk managers, and executive stakeholders with the goal of mapping functional roles in attack chains and TTPs (Tactics, Techniques, and Procedures). Understanding how these malicious polyglots are constructed is key to developing effective defenses. What follows are several taxonomy categories, their definitions, and examples to facilitate understanding. These include structural taxonomy, semantic taxonomy, and operational taxonomy.

Structural taxonomy defines the organizational structure of a polyglot file. This includes sequential polyglots, where two or more complete files are placed back-to-back, relying on parsers to ignore trailing data, which can bypass file type validation and allow lists. Another type is embedded or container-based polyglots, where one valid file format is contained within the data fields of another while both remain compliant. This allows for data transmission by surviving compression and metadata rewriting. Finally, interleaved polyglots involve the

same bytes being interpreted differently by two parsers due to overlapping semantic meaning. The technique can be used to evade or break parser-based detection, static analysis, or machine learning extraction.

Semantic taxonomy defines how definitive security measures fail or are evaded by the polyglot. Type-confusion polyglots are characterized by a mismatch between the declared file type and the actual parser behavior, serving as an evasion vector for magic-byte identification or file upload validation and enabling downstream abuse. Inspection-evasion polyglots occur when security tools inspect only one semantic interpretation of the file while ignoring others, allowing the polyglot to achieve persistence even in inspected environments. Context-switch polyglots are benign in one operational context but become malicious in another, which allows for delayed or cascading exploitation while evading shallow assessments without breaking workflows.

Operational taxonomy maps polyglots into specific attack usage scenarios. Ingress polyglots are used specifically for smuggling across security boundaries. A persistence polyglot has the purpose of surviving archival, sharing, or long-term storage without triggering alerts. Lastly, activation polyglots are designed with the specific purpose of being activated through a pipeline, workflow, or some form of triggered automation.

Together, these provide perspectives on how polyglots should be analysed-not as mere anomalies in file formatting but as intentional malicious instruments used to pry exploitable gaps between file semantics, defensive tooling, and system trust boundaries.

3. Feasibility Demonstrated: The Operationalized DICOM Polyglot

3.1 Methodology and Research Environment

For the purpose of this work, a table of components used in the investigation is provided. These help the audience to have a sense of what is needed to replicate findings and what to look for. Parameters are default.

Table 1: Components used for this investigation

Item	Definition	Purpose	Version
Malware Bytes	Commercial endpoint anti-malware solution	Evaluated local static detection behavior of constructed artifacts	5.4.7.229(Component Package 148.0.5470)
Orthanc server	Open-source DICOM server implementing DICOM storage and query/retrieve services	Used to simulate PACS ingestion, storage behavior, send studies via STOW, and reserialization of DICOM objects	1.12.9
Weasis Medical Viewer	Open-source DICOM viewer	Used to validate image rendering and observe viewer handling of modified DICOM objects	4.6.3
HxD Hex Editor	Low-level binary file editor	Used for byte-level inspection and structural modification of file regions for crafting the exploit	2.5.0.0
Windows 11	Host operating system environment	Used to evaluate file association behavior, invocation context, and endpoint inspection responses	24H2 (OS Build 26100.7623)
MinGW-w64 GCC 13.2.0	C code compiler	Used to compile executable Windows PE code	13.2.0

This paper looks at the potential uses of polyglot file techniques in relation to the DICOM Part 10 file structure, as discovered by d00rt (Ortiz, M.O.,2019). Our research was executed in three phases. The first phase defined a taxonomy of the structural, semantic, and operational attributes for polyglot files. This phase also placed the category of DICOM-based polyglot files within the existing body of research concerning different types of file formats.

The second phase of the work involved an analysis of the DICOM Part 10 file structure, specifically examining the preamble, file meta information, dataset encoding, and private data elements. These components were

utilized to assess the susceptibility to potential polyglot exploitation and to identify areas where dual-valid constructs could exist while maintaining compliance with the DICOM Data Dictionary.

In the third phase, controlled laboratory DICOM polyglots were created. Payload artifacts were written in C/C++ and compiled into Windows Portable Executable (PE) binaries, using MinGW-w64 GCC 13.2.0 on Windows 11, to be embedded as test payloads. The payloads were embedded into anonymized, functioning DICOM part 10 image files while maintaining structural validity using the tools and environment from Table 1.

Evaluation of the polyglot behavior across ingestion, archival, inspection, and detection workflows was completed to monitor how polyglots would interact with common medical imaging environments. Using a fully patched and updated Windows 11, the objects were scanned by Defender and Malwarebytes to observe end point detection. They were then placed in a directory and uploaded as a study via Orthanc using STOW to be stored in a receiving Orthanc DICOMweb server for storage. This step was done to observe possible alteration to the file that may occur during ingestion. The items were then rescanned by Defender and Malwarebytes, checked for executability on windows or Linux machines, and lastly, tested for the ability to be viewed as an image in Weasis.

The paper includes a description of the research environment, tools used for construction and validation, and static analysis results to illustrate detection variability. Findings are interpreted through the S.P.I.C.Y. model-Stealthy, Polyglot, Infiltrative, Cascading, Yield-to formalize how such artifacts function in offensive simulations. The goal is not to promote exploit development, but to provide a structured framework for evaluating data-centric threat surfaces that may be overlooked in conventional security training focused primarily on network and credential compromise.

3.2 DICOM Vulnerability Context

A DICOM file structured according to the Part 10 file specification is constructed of four primary components: a preamble, a file prefix, the file meta information, and the actual data set. The preamble, the set of initial 128 bytes, which for the DICOM Standard is unutilized space, often filled with null bytes, and is reserved for third party or application specific purposes. This section is designed to maintain compatibility between DICOM part 10 files and software or legacy systems that may rely on a specific header offset. This is a characteristic that will later become significant for exploitation.

Following the preamble, a four-byte prefix with the string 'DICOM' provides the file signature, a particular set of characters used to explicitly identify the file as a valid DICOM Part 10 file. The third main section is the File Meta Information. This section exclusively contains data elements from the group (0002, xxxx) and is mandatorily encoded with an Explicit VR Little Endian transfer syntax, irrespective of the encoding applied to the subsequent data set. Important elements within the File Meta Information include the Media Storage SOP Class UID, Media Storage SOP Instance UID, Transfer Syntax UID, and Implementation Class UID. The Transfer Syntax UID specifies the encoding method for the remainder of the data set. This includes byte ordering (Little-endian or Big-endian) and whether Value Representations are explicit or implicit. The final and largest component of the DICOM file is the dataset. This segment of the file contains the data elements representing metadata and the pixel data of the images. It is a collection of all the data elements encoded given instructions in the Transfer Syntax. Every Data element may be broken down further into four sub-components or fields. The first is the Tag, a numeric identifier consisting of the group number and element number. Next is the Value Representation, which is only included with explicit VR encoding. Third, is the Value Length, a parameter that specifies the length in bytes of the value field. Finally, the Value Field which contains the stored image data.

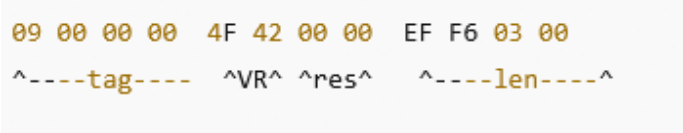

Figure 1: The Private Tag

DICOM files are structured using a series of Data Elements, each uniquely identified by a tag comprising a group number and an element number (Figure 1). Each Data Element possesses a Value Representation (VR), which specifies the data type (e.g., text, numeric, sequence), and a Value Length, indicating the size in bytes. The encoding, including byte ordering, is governed by the negotiated Transfer Syntax. This rigid yet flexible layout ensures reliable parsing across different systems while accommodating the wide variety of medical data stored in DICOM files. The format distinctly separates public and private Data Elements. Public Data Elements

are formally defined within the DICOM standard and utilize even-numbered Group Values. Conversely, private Data Elements employ odd-numbered Group Values, reserved for vendor-specific or third-party usage. Prior to utilizing private Data Elements, a vendor must first define a Private Creator Data Element to reserve a range of Data Element Numbers for proprietary use. This mechanism facilitates the embedding of proprietary metadata without compromising adherence to the DICOM standard. While compliant systems typically include and transmit private Data Elements as-is, they are not necessarily interpreted unless the receiving application can access the associated private dictionary. Consequently, when this access is unavailable, the private data can appear as an opaque entity to external parties, intended for another system. This phenomenon can occur throughout the entire processing pipeline, including ingestion, archival, forwarding, and viewing, meaning that private fields, regardless of their source or format, may pass through without detailed examination.

The customizable attributes permitted by the DICOM format, while offering flexibility for interoperability, introduces an inconsistency in the level of scrutiny of compliant data elements. Public data elements are typically well-defined and normally validated, but private fields may contain data in an arbitrary format. The private field formats may only be known to the vendor creating an issue where the code is opaque to any DICOM parser and may not be analysed. Given the increasingly mixed applications and development of clinical environments where images traverse multiple platforms, a valid private field can persist unchanged for an indefinite amount of time and processing. This allows private Data Elements to potentially embed tertiary data structures while remaining a valid DICOM object. The associated risk stems not from DICOM's specifications but from the asymmetry between the application of the extensibility and the failure to consistently validate private data elements throughout the medical image pipeline.

3.3 Proof of Concept: Constructing the Dual-Valid Artifact (Technique Validation)

Here in Figure 2, we can see the first 128 bytes of a Dicom file with the first 26 bytes over-written with a Bash script. By using the hex editor application HxD, we are able to alter the hex code of the file to add the script. It contains the '#!' of the bash script followed by a basic whoami command and a proper exit from the script. This allows the DICOM file to now function as a DICOM image collection and a bash script. This is our first example of a DICOM polyglot proof-of-concept. Its simplicity in creation means that automation and prolific generation would take small amounts of resources, time, or effort.

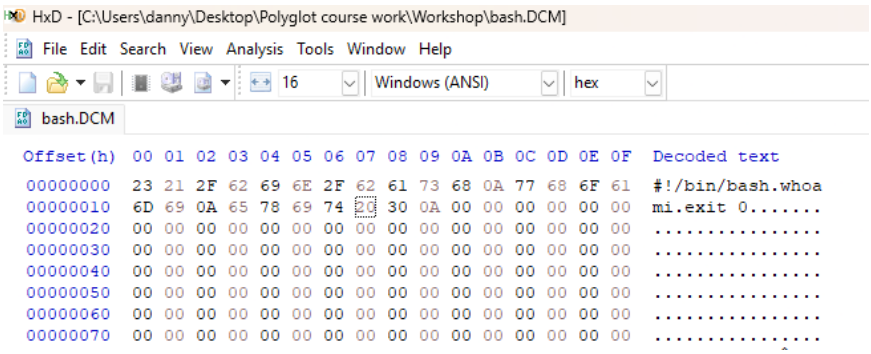

Figure 2: HxD table: An initial example illustrating the exploitability of DICOM and its utility as an ingress vector involves abusing the preamble. The first 128 bytes of the DICOM preamble are commonly ignored by data parsers. This vulnerability permits the injection of any file up to 128 bytes, which most DICOM parsers will subsequently disregard

The next part of the DICOM part 10 File we will attempt to demonstrate as exploitable is the Private tag. In this example we will use both the 128-byte preamble and the private tag data element in conjunction to create a working DICOM/PE (Portable Executable) file.

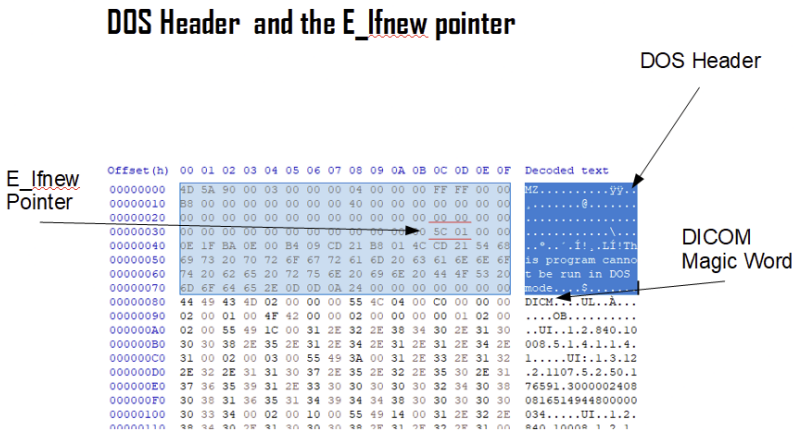

Figure 3: DICOM Magic Word, (File Signature), DOS Header, and E_lfnew Pointer locations in the Hex code.

In Figure 3, we can see how the DOS header of the PE perfectly fits into the blank Preamble of the DICOM. Leveraging the PE e_lfnew Pointer, we can redirect the PE flow to the PE file signature. If the pointer is used to point further into the DICOM file toward data embedded in a private element identified with a private tag, we can place the remainder of the PE inside this Data element and with a high likelihood it will not be parsed by most DICOM viewers. Further alteration of the private tag to match length, adding proper padding to the PE to ensure alignment, and altering the remaining PE pointers to the correct offsets will now allow a PE to function while not disrupting the DICOM data structure (Figure 4).

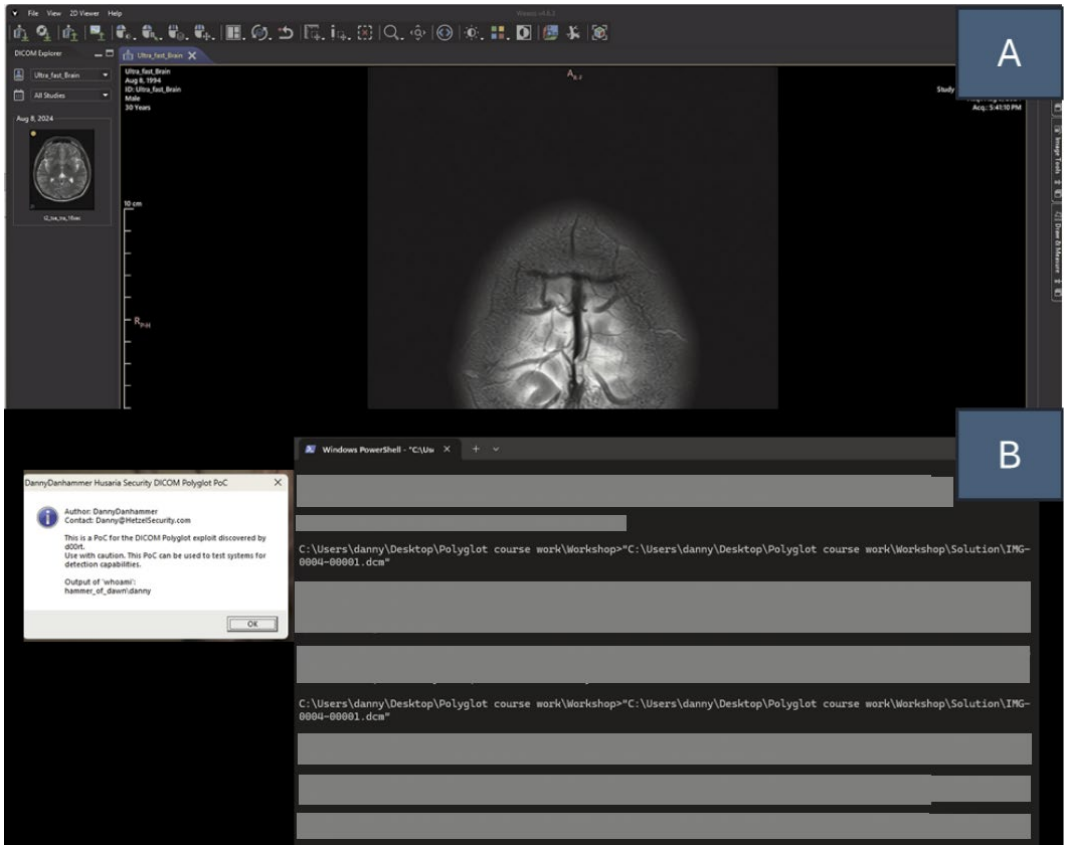

Figure 4: DICOM Image and Execution: A) The DICOM image opens with the associated DICOM parser with a double click. B) But when opened via the terminal it executes out payload PE. (Unnecessary terminal commands redacted provide focus.)

4. The Operational Gap: Why Feasibility Translates to Risk

4.1 Non-Uniform Inspection and the Stealthy/Polyglot Gap

A key defining characteristic of polyglots is their chameleon-like ability to remain syntactically valid under multiple file formats simultaneously (Albertini, 2015). Their dual, and sometimes ternary, validity introduces a challenge for security tools that assumes a file conforms to a single format. In healthcare imaging environments, where DICOM objects are commonly treated as clinical data rather than untrusted adversarial inputs, prioritization of schema conformance and renderability by inspection mechanisms is seen rather than full byte-stream analysis. As such, data artifacts containing multiple semantic interpretations may not be consistently classified across security tools.

Observations from the feasibility phase of this study illustrate this asymmetry in inspection. The polyglot proof-of-concept developed in Section 3 was analysed using the multi-engine malware analysis tool VirusTotal and the endpoint detection software Malwarebytes. VirusTotal had a mixed reporting of 11 out of 71 security tools reporting as possibly malicious (Figure 5). While a score of 11/71 would raise suspicions to many, the inability to run DICOM through public scanners and requiring the choice of a local antivirus software, creating an environment where evasion only needs to succeed in 1 or the 71 presented. This places a higher importance on the failure to detect proportion from 84.51% of assessed antivirus products. When executed within heuristic-capable sandboxes on VirusTotal, the polyglot triggered only seven low-severity and three informational MITRE signatures, despite performing indirect command execution and process injection. Although VirusTotal was able to identify the polyglot through aggregated results, many mainstream security tools failed to detect it independently.

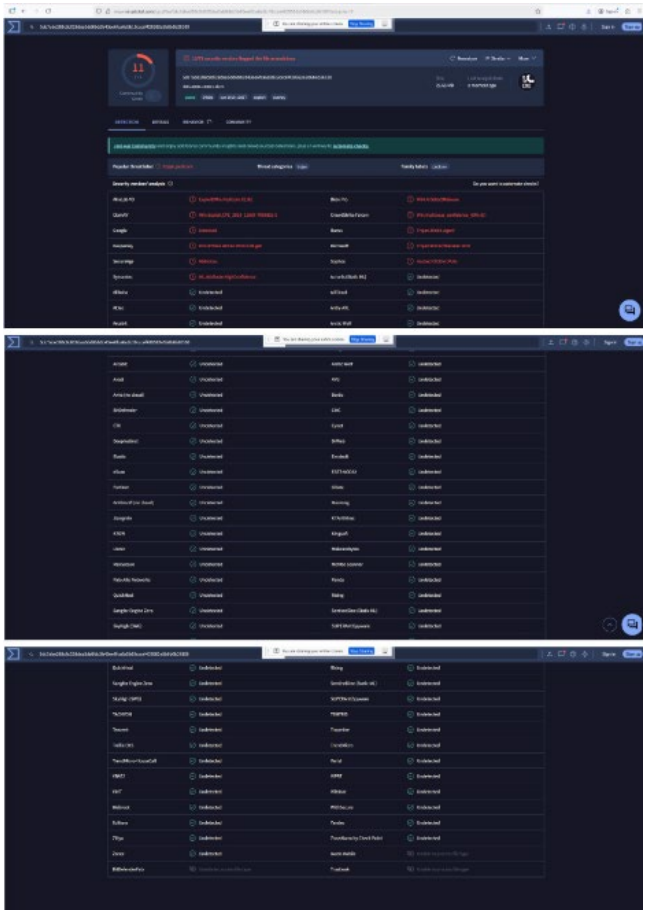

Figure 5: A) Analysis of the artifact using VirusTotal. The VirusTotal report indicates that 11 security providers (highlighted in red) successfully identified the artifact, while numerous other providers failed to detect the exploit, despite its relationship to a widely recognized vulnerability

To further assess the local endpoint detection behavior, the polyglot was scanned using Malwarebytes (version 5.4.6.227) in a controlled environment. At the time of the test, Malwarebytes reported no detection (Figure 6).

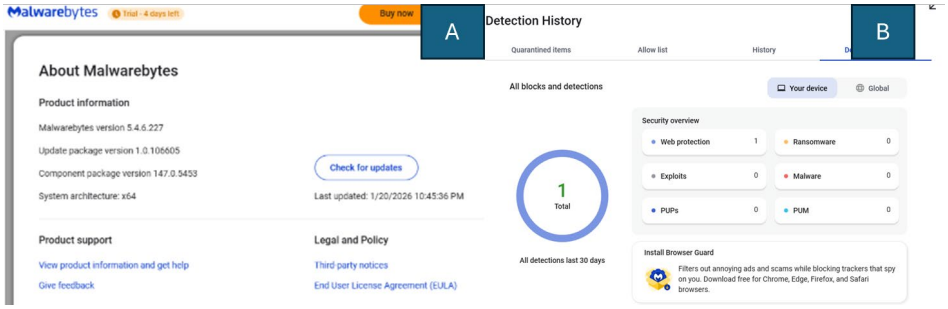

Figure 6: A) Malwarebytes, a consumer anti-malware program. B) Diagnostic screen demonstrating failure to detect the artifact

This gap indicates that different security products interpreted the polyglot file according to different assumptions and approaches to parsing. Some products readily identified byte patterns associated with executable structures embedded in the file and within the preamble. Others accepted the format presented as a simple DICOM object and did not do further analysis to uncover the patterns of possibly obfuscated code. This is not attempting to illustrate a failure of this specific product but rather the lack of uniformity in detection. Previous research has highlighted product to product inconsistencies are deeply ingrained (Mohaisen and Alrawi, 2014). Antivirus products fundamentally disagree with each other on both detection and labelling, to a degree that makes their outputs, by themselves, unreliable as ground truth. Classification of multi-format or polyglot files may not be reliably detected by a single security product. Polyglots exploit this ambiguity by presenting different semantic interpretations depending on the parsing logic applied. A polyglot does not need to evade all security tool detections to succeed operationally. It must only pass through enough stages of inspection to enter the trusted workflow. In this sense, stealth arises not from sophisticated obfuscation techniques but from classification ambiguity. Within the S.P.I.C.Y. model, this represents the intersection of the Stealthy and Polyglot characteristics: the polyglot file remains structurally compliant while different systems disagree about its interpretation. This inconsistency can be operationally significant. In the complex enterprise environment, security controls rarely rely on a single security tool or inspection method. As files move through different systems and scanners, each applying its own parsing logic, the likelihood of inconsistent classification increases.

4.1.1 The standards non-operational state

After 7 years of existing as a known vulnerability, the persistence of this gap reflects a broader systemic issue within the healthcare ecosystem, as opposed to a flaw in DICOM standard itself. DICOM was designed as a tool to offer interoperability across diverse imaging devices and software platforms. To accomplish this feat, the standard permits extensibility. Extensibility is achieved through features of the standard such as vendor specified private tags and flexible metastructures. (National Electrical Manufacturers Association (NEMA), 2026). These features enable vendors to embed proprietary information while maintaining compliance with the standard. This extensibility also introduces ambiguous areas within the file that creates issues for uniformity in parsing.

In practice, many implementations of "DICOM validation" focus on verifying structural conformance or the ability of imaging software to render the imaging data correctly (Mirsky et al., 2019). Parsers and viewers, such as Weasis, only focus on the imaging and ignore unnecessary sections of data. While these checks are essential for interoperability, they do not necessarily enforce deep comprehensive inspection of the entire object. The result is what can be described as a non-operational security state. The format's extensibility is fully implemented but the corresponding security validations are not consistently enforced across tools or environments. Several factors contribute to this condition further. Complete comprehensive semantic and structural inspection of every DICOM object can be computationally expensive and could result in latency in critical clinical workflows and pipelines. Next, traditional healthcare security architectures acknowledge the dangers of ingress points of email attachments, web downloads, and others, but imaging data pipelines are often treated as trusted channels (Mahler et al., 2018).

To properly address this operational gap requires moving beyond the assumption that format compliance alone guarantees safety within trusted workflows. Standards bodies, vendors, and healthcare operators must consider approaches that apply more thorough validation practices. Potential directions include establishing baseline expectations for byte-stream inspection of DICOM objects, defining clearer policies for handling

private data elements, and developing security-focused conformance profiles that can be implemented consistently across heterogeneous systems. Such efforts would not eliminate the flexibility that makes DICOM interoperable but would help ensure that this flexibility does not translate into systemic blind spots within clinical imaging workflows.

4.2 Automated Pipelines and the Infiltrative/Cascading Gap:

While the inconsistent inspection and parsing in security tools has shown how such objects can evade detection, feasibility alone cannot translate into operational risk, the polyglot must have the ability to traverse real workflows. Modern medical Imaging infrastructure in healthcare environments are not static storage. They are interconnected data pipelines in which DICOM objects move through multiple automated systems over the course of its lifecycle (Pianykh, 2012). A single image study may originate from an imagining source ,such as a MRI scanning system, pass through ingestion services (Store-SCP or DICOMweb STOW), enter a Picture Archiving and Communication System (PACS), be transferred into a long term archival system such as Vendor Neutral Archive (VNA) and finally be accessed by diagnostic viewers , exported to research sets, or even processed by artificial intelligence and machine learning pipelines (Kahn, 2016). Throughout the course of its lifecycle, the DICOM object is repeatedly parsed, indexed, modified, and redistributed by automated systems (Pianykh, O.S., 2012).

For the S.P.I.C.Y. model, this corresponds to the Infiltrative and Cascading phases of the lifecycle. This infiltrative phase occurs when a polyglot object enters the pipeline through legitimate ingestion. Because the polyglot follows the syntax and structural requirements for the DICOM File part 10 specification, systems that rely primarily on structural validation may accept the object without detecting its secondary semantics (Pianykh, 2012; Huang, 2018). The cascading occurs when the polyglot is parsed and pushed through multiple steps of the pipeline while being able to maintain its malicious capabilities (Mirsky et al., 2019; Mahler et al., 2018). Within this framework, the infiltration and persistence become properties and assets of the workflow rather than of a single exploit. Using the ambiguity of the heterogenous workflow that due to assumed trust, the accepted structurally valid polyglot may propagate throughout the environment, through multiple systems, that independently interpret the same data, allowing the Stealthy and Polyglot characteristics of the S.P.I.C.Y. model to persist across the pipeline.

5. Discussion: Activation, Yield, and Strategic Implications

5.1 Activation Context in Automated Workflows

The execution and activation of a DICOM polyglot does not require manual user double-click. In healthcare environments, as discussed in section 4, there are numerous contexts in which a DICOM object might be parsed. Dicom objects are routinely processed by automated systems outside simple graphical viewers. These interactions can occur through command-line utilities, batch processing scripts, research pipelines, and more recently into machine learning and AI contexts. At each step the possibility of execution based on varying interpretation may occur because each system may apply different parsing assumptions to the same byte stream.

This inconsistent nature of the different forms of interpretation creates the conditions necessary for execution or activation. A viewer may see a plain DICOM image to be displayed, while another subsystem or script may interact with the same object and interpret the same data differently by the embedded syntax. This disparity forms the path to polyglot execution. A file, now embedded deep within the architecture and having crossed multiple trust boundaries, may be invoked through command-line tools, scripting environments, or automated data transformation processes.

Recent practitioner work suggests that the process to create such polyglots will become increasingly automated. Aguilar (2026) and Davis (2026) describe a proof-of-concept toolkit of embedding crafted malicious Windows Portable Executables (PE) binaries within valid DICOM images through an automated process and leveraging and merging further advanced evasion tactics. Invoked through command-line contexts while remaining undetected through automated creation and built in features including beaconing. Although the toolkit has not been formally released or subjected to peer review, its existence presents an important operation leap forward from the manual creation presented in this paper: The technical barrier to constructing DICOM polyglots is decreasing and automation of the threat is becoming a significant reality. As tooling matures, the threshold for adversarial use is decreased.

5.2 Redefining Yield: The Scope of Damage:

Conventional exploit analysis often measures success primarily in terms of payload execution. Within data-centric attack surfaces, yield must be understood more broadly. Operational value from a polyglot can extend beyond execution by successfully entering and persisting within trusted workflows. Successful ingestion and persistence demonstrate that the artifact can survive inspection boundaries and remain structurally intact. These conditions create the opportunity for later activation through lateral vulnerabilities within the system.

Under the S.P.I.C.Y. model, yield asks what the operational value is gained once a polyglot artifact successfully traverses trusted workflows. The most direct outcome is achieving execution when the polyglot is interpreted in a specific execution context. Yield may also arise from the persistence described previously, as the ability of the polyglot to remain embedded within trusted workflows enables adversaries to position executable objects deep inside clinical infrastructure. From a defensive perspective, this broader definition of yield is critical. It repositions analysis of the threat from a binary condition of exploit success or failure into a graduated model of system exposure.

5.3 Strategic Implications and Mitigation

The use of DICOM polyglots in threat exercises challenges the assumption that medical data is inherently non-executable; this finding fits within the understanding of biocentric data, media, and platforms being relevant for attack chains (Mueller, 2021; Potter and Palmer, 2023; Pope, 2026). Medical images were designed to ensure reliability and interoperability between software, platforms, and devices. As a result, security controls have often developed behind these design principles in prioritization. Business needs and attempting to support legacy systems has left an operational gap in detection. When a file satisfies the structural requirements of the DICOM standard, generally, it is treated as a valid medical object and allowed to proceed through the workflow as a trusted object. This design philosophy has operational consequences and, in those consequences, lies the gaps that researchers and adversarial actors will eventually discover and leverage; further commentary follows in Figure 7.

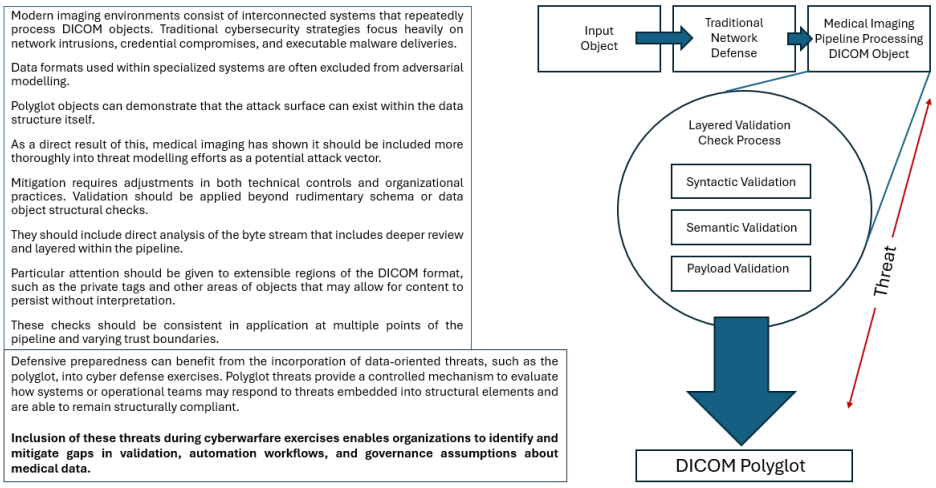

Figure 7: Design and preparedness philosophy commentary around DICOM Polyglots

The S.P.I.C.Y. framework offers a guided approach for evaluating these scenarios. Through examining how an artifact remains stealthy, infiltrates trusted workflows, cascades across connected systems, and produces operational yield, defenders can better understand how data-layer threats affect healthcare infrastructure. Using S.P.I.C.Y. as a guide creates an avenue for organizations to overcome the gaps presented by the traditional exploit models and help them move toward a broader understanding of how trusted data structures and standards can be abused to become attack surfaces. Avenues created through the use of guides such as these potentially create opportunities for healthcare organizations to improve perceptions of patient and provider sense of security, within a world that is increasingly subject to healthcare-centric cyber-attacks (Griffin et al, 2026).

6. Limitations and Future Works

The paper lacks empirical experimental data to aid exact reproducibility. The choice to limit this data is due to the nature of harm that could be weaponized and data hazards that could be produced with replication of the

experiment. Upon responsible request and discussion, a guided walkthrough to aid in reproducibility can be obtained from the author. While it may appear that the tools used were rather limited, VirusTotal comprises 70+ tools, thus mitigating this concern. Future work involves generation of a larger proof-of-concept dataset which can be tested for detection by security analysis tools. This will result in the ability to create a more quantified and firmer consensus to the state of DICOM polyglot detection in industry tools.

7. Conclusion

This paper has shifted the discussion around DICOM polyglots from technical feasibility to unmitigated operational risk within healthcare workflows, highlighting a critical security gap stemming from non-uniform inspection, misplaced trust in data compliance, and insufficient threat modelling. Our feasibility analysis, using a controlled DICOM/PE polyglot, demonstrated that mainstream security tools exhibit substantial inconsistencies in detection, allowing these dual-valid artifacts to remain stealthy. To address this, we introduced the S.P.I.C.Y. framework as a tool for practitioners to measure the operational impact of malicious data propagation through trusted, automated pipelines like PACS and VNAs. The framework emphasizes that yield extends beyond execution to include the operational value gained from persistence deep within clinical infrastructure. Ultimately, mitigating this systemic risk requires moving beyond the assumption that format compliance guarantees safety, urging standards bodies, vendors, and operators to apply consistent, byte-stream-level validation across the entire medical image lifecycle to close the operational blind spots exposed by data-centric threats.

Ethics Declaration: Clearance for the research within this paper was not required and no humans were affected.

AI Declaration: Grammarly and Google Docs and AI tools within were used for formatting and overall re-organization.

An Integrated Framework for Ransomware Mitigation: A NIST-Aligned Defense Model Linking Cyber Insurance and Risk Management

Li Huang and Kimberly A. Cornell
University at Albany, USA

lhuang9@albany.edu
kacornell@albany.edu

Abstract: Ransomware attacks have become one of the most disruptive cyber threats to modern organizations, causing significant financial losses, operational disruptions, and reputational damage across sectors. While organizations increasingly adopt security measures to mitigate risks, the fast-evolving role of cyber insurance-supported mitigation services in ransomware defense remains insufficiently understood. Cyber insurance has evolved from just a reactive compensator to a proactive security partner. It now offers pre-incident services to mitigate attack severity and post-incident services for quick recovery, reducing loss impacts. Cyber risk management and cyber insurance practices are often divided among different disciplines. Actuarial underwriting seldom integrates risk management models, and cybersecurity experts rarely include insurer mitigation tools in governance plans. This disjointed approach restricts organizations from effectively using insurance services as part of a comprehensive ransomware resilience strategy. This study investigates how cyber insurance-supported services aligned with the NIST Cybersecurity Framework reduce the impact of ransomware incidents. Building on prior empirical research identifying socio-technical drivers of ransomware losses, this paper proposes an integrated mitigation framework that combines security governance functions with insurance-supported services including vulnerability assessment, forensic readiness, incident response coordination, and recovery assistance. The framework conceptualizes ransomware risk mitigation as a layered process in which socio-technical risk drivers shape both the likelihood of incidents and the effectiveness of mitigation mechanisms. By incorporating the socio-technical factors that shape the impact of ransomware incidents, the proposed framework provides a more comprehensive defense posture against ransomware threats. Through analytical modeling and scenario-based evaluation, this study demonstrates how coordinated implementation of NIST-aligned cyber insurance services can significantly reduce expected ransomware losses and accelerate organizational recovery. The findings emphasize integrating technical cyber practices with insurance expertise to strengthen cyber resilience. By linking cyber risk management and insurance, this research enhances understanding of ransomware mitigation and offers practical insights for organizations managing ransomware risks in a rapidly evolving threat landscape.

Keywords: Ransomware Attacks, NIST CSF, Cyber Insurance Service, Integrated Framework, Risk Mitigation

1. Introduction

Ransomware attacks have become one of the fastest-growing cybercrimes in the digital economy (Sausalito, 2024). Organizations across industries increasingly rely on information systems to support critical operations, making them attractive targets for cyber adversaries. Cybercriminals use ransomware to encrypt victims' sensitive information and threaten to publicly release the information unless a ransom payment is made (August, et al., 2019; OZ, et al., 2022). Recent reports indicate that ransomware incidents continue to grow in frequency and severity, leading to billions of dollars in economic losses each year (Cartwright & Cartwright, 2023). Ransomware attacks can disrupt essential services, compromise sensitive data, and undermine trust in digital infrastructure (Dawson, et al., 2021). As tactics evolve toward professionalized models a variety of crimes like double and triple extortion, supply-chain propagation, and Ransomware-as-a-Service have emerged that traditional cybersecurity defenses alone are often insufficient to mitigate ransomware impact (Nagar, 2024).

To address this threat, many technology-based solutions have been developed to protect information assets (Hegde & Rokseth, 2020). As ransomware attackers target vulnerabilities in system and employee behavior, non-technical factors have become crucial in cyber defense (Nagar, 2024; Shaikh, et al., 2024). Various management frameworks address the growing complexity of cyber-attacks (Rassam, et al., 2017). These frameworks guide organizations in managing cyber risks, incident handling, and prevention. Organizations select frameworks or combinations that suit their needs to enhance cybersecurity and protect digital assets. The NIST Cybersecurity Framework (CSF) is widely used, categorizing practices into five domains: Identify, Protect, Detect, Respond, and Recover (NIST, 2022). These domains provide an approach to organizations for managing cyber risks across the entire lifecycle of a cyber incident (NIST, 2022).

Cyber insurance has been evolving beyond the traditional insurance paradigm to embrace security expertise (Huang & Cornell, 2025; Zywave, 2025). Risk services alongside cyber insurance policies help prevent potential

threats and mitigate the impacts of cyber incidents (Zeller & Scherer, 2023). Cyber insurance in recent years has increasingly evolved into a provider of cybersecurity expertise and mitigation services (Huang & Cornell, 2025; Zywave, 2025; Blackfog, 2024). Modern cyber insurance policies often include pre-incident and post-incident support such as vulnerability assessments, incident response coordination, digital forensics, and recovery assistance (Zeller & Scherer, 2023). These services position insurers as active participants in cybersecurity governance rather than passive claim processors (Huang & Cornell, 2025; Blackfog, 2024). As cyber threats continue to escalate, the role of cyber insurance is shifting toward a more proactive model that emphasizes prevention and resilience. This proactive capability may help position cyber insurance in a more central position in cyber risk management.

Despite advancements, a gap still exists in understanding how cyber insurance reduces ransomware risks. Existing literature mainly examines technologies, governance frameworks, or cyber insurance mechanisms independently (McIntosh, et al., 2021). Technical studies typically focus on detection algorithms, system hardening, or network defense mechanisms, while economic and actuarial research examines cyber insurance pricing and risk transfer (Martin & Collier, 2020). Ransomware mitigation is inherently socio-technical requiring coordination between technical defenses, organizational practices, and financial risk management mechanisms (Mukhopadhyay & Jain, 2024). The effectiveness of ransomware mitigation strategies may depend on socio-technical conditions within organizations. For example, organizations with stronger security governance may be able to leverage incident response services more effectively, while highly interconnected organizations may face greater challenges in containing ransomware propagation. Previous work does not fully capture how mitigation effectiveness emerges from the interaction between internal governance mechanisms and external risk management services under varying organizational conditions. This fragmentation limits the theoretical understanding and practical application of defenses.

This study examines how cyber insurance-supported services aligned with the CSF mitigate ransomware impacts. Incorporating socio-technical drivers of ransomware losses, the paper proposes an integrated analytical framework that links organizational risk drivers, cybersecurity governance functions, and insurance-supported mitigation services. Mitigation effectiveness is conceptualized as the outcome of coordinated security controls and insurance services operating across the ransomware attack lifecycle. The central theoretical contribution lies in demonstrating that mitigation effectiveness is not additive but interactional, where the marginal benefit of one mechanism depends on the presence of the other and is further conditioned by socio-technical factors such as organizational preparedness, technological posture, and network exposure. By formalizing these relationships, this study goes beyond descriptive integration and provides a structured explanation of how coordinated mitigation strategies produce non-linear reductions in ransomware impact. To our knowledge, this is among the first studies to formally model the interaction between cybersecurity governance and insurance-supported mitigation services in complex socio-technical environments.

The rest of this paper is organized as follows. Section 2 reviews related literature on ransomware risks, cybersecurity frameworks, and cyber insurance services. Section 3 presents the integrated mitigation framework and analytical model. Section 4 presents scenario-based analysis demonstrating the effectiveness of coordinated mitigation mechanisms. Section 5 discusses implications for cybersecurity governance and cyber insurance. Section 6 concludes with future research suggestions.

2. Literature Review

Ransomware has increasingly become a targeted attack, where attackers carefully select victims based on system vulnerabilities and data sensitivity (OZ, et al., 2022). As a result, socio-technical factors such as technical infrastructure, organizational readiness, and operational processes are vital in determining the impact of ransomware attacks (Haimes, 2012; Zhang, et al., 2011; Anderson & Moore, 2006). These factors not only influence the severity of ransomware incidents but may also affect the effectiveness of mitigation strategies. Addressing these factors is essential for accurate risk assessments and for proactive defense implementations. While previous studies highlight socio-technical factors in ransomware outcomes, many are descriptive and lack explicit links to mitigation effectiveness. They offer limited analysis of how organizational conditions affect mitigation mechanisms and loss severity, restricting practical risk management insights.

To address these complex cyber risks, organizations often rely on structured governance frameworks. Among the most widely adopted frameworks is the CSF, which provides a structured approach for identifying, assessing, and mitigating cybersecurity threats (NIST, 2022). Existing literature examines cybersecurity frameworks in strengthening organizational cyber resilience (Tsen, et al., 2022). However, these frameworks mainly emphasize technical and organizational controls within the firm. While providing valuable guidance for managing cyber risks,

they often do not explicitly incorporate external risk management mechanisms such as cyber insurance. Existing studies primarily emphasize internal governance structures and technical controls, treating organizations as self-contained units of defense. As a result, existing frameworks may overlook the wider ecosystem of actors involved in cyber risk mitigation.

Cyber insurance was initially a financial tool to compensate organizations for cyber losses (Blackfog, 2024). It has evolved to offer more cybersecurity services (Zywave, 2025; Huang & Cornell, 2025; Blackfog, 2024). Now cyber insurance provides pre- and post-incident risk assessment services, including vulnerability assessments, security audits, legal guidance, and response coordination (Zeller & Scherer, 2023). As incidents have increased in frequency and sophistication, cyber insurance has become more involved in helping organizations manage cybersecurity risks proactively (Mukhopadhyay & Jain, 2024). Cyber insurance increasingly functions as a risk advisor that supports organizations throughout the cybersecurity lifecycle. While industry reports highlight this service-oriented shift (Zywave, 2025), academic literature seldom explores how these services affect security controls or their impact on mitigation in various organizational contexts. This gap suggests the need for a more integrated analytical perspective that connects insurance-supported services with cybersecurity frameworks and socio-technical risk factors.

Although substantial research exists on ransomware, cybersecurity frameworks, and cyber insurance, these areas have largely developed independently. Technical ransomware research has focused primarily on detection algorithms, encryption mechanisms, and system defense strategies. Actuarial research on cyber insurance has concentrated on risk pricing and contract design. Few studies examine how insurance-supported mitigation services interact with governance frameworks under varying socio-technical conditions.

This study develops an integrated framework linking socio-technical ransomware risk drivers with NIST-aligned cyber insurance services. It aims to enhance understanding of ransomware mitigation strategies in modern cyber risk environments.

3. Conceptual Framework

While cybersecurity frameworks provide guidance for implementing technical and governance controls, cyber insurance offers additional resources and expertise that can support organizations in preventing, responding to, and recovering from cyber incidents. This study proposes an integrated mitigation framework that links cybersecurity governance functions with cyber insurance-enabled mitigation services to reduce ransomware impact. The proposed framework conceptualizes ransomware risk mitigation as a layered system consisting of three primary components: socio-technical risk drivers, cybersecurity governance mechanisms, and insurance-supported mitigation services. These components jointly determine the effectiveness of mitigation actions and ultimately influence ransomware outcomes.

3.1 Socio-Technical Drivers of Mitigation Effectiveness

Socio-technical conditions within organizations play an important role in determining the effectiveness of ransomware mitigation strategies (Mukhopadhyay & Jain, 2024). Cybersecurity systems operate within complex organizational environments where human behaviour, technological infrastructure, and organizational processes interact (Neoaz, 2024). Consequently, the same mitigation mechanisms may produce different outcomes depending on organizational conditions.

- Organizational preparedness refers to the extent to which an organization has established cybersecurity governance structures, security awareness programs, and incident response planning capabilities. Organizations with stronger preparedness are better positioned to implement cybersecurity controls and respond effectively when ransomware incidents occur (Haimes, 2012).
- Technology posture reflects the quality and robustness of an organization's technological infrastructure, including system architecture, patch management practices, and network security configurations. Weak technological infrastructure may create vulnerabilities that ransomware attackers can exploit, thereby increasing both the likelihood and severity of incidents (Zhang, et al., 2011).
- Settlement duration captures the time required to resolve ransomware incidents, including negotiation processes and system restoration efforts. Longer settlement durations often indicate more severe operational disruption and may increase overall financial losses (Anderson & Moore, 2006).

- Network exposure represents the extent to which organizations are connected to external partners, vendors, and digital supply chains. Highly interconnected systems may increase the potential for ransomware propagation across networks, making containment and recovery more difficult (Robinson, et al., 2022).

These socio-technical factors influence ransomware mitigation in two ways: they impact the likelihood and severity of ransomware incidents, and they shape the effectiveness of mitigation mechanisms implemented through cybersecurity frameworks and insurance-supported services.

3.2 Integration with CSF and Cyber Insurance Services

The framework integrates ransomware-relevant mitigation strategies across the five functions of the CSF, demonstrating how technical controls, governance practices, and cyber insurance services operate together throughout the ransomware lifecycle. Table 1 organizes the proposed framework along two dimensions: (1) the five functional domains of the CSF, and (2) three complementary layers of mitigation, cyber insurance-supported services, internal cybersecurity controls, and socio-technical influencing factors. Rather than representing independent components, the table illustrates how these elements operate jointly within each stage of the ransomware lifecycle. Specifically, each column represents a governance phase (from Identify to Recover), while each row highlights how different mitigation resources and contextual conditions contribute to reducing ransomware risk within that phase. This structure emphasizes that mitigation effectiveness emerges from the coordination of technical controls, external expertise, and organizational conditions rather than from any single mechanism in isolation.

Table 1: Integrated Framework

NIST	Identify	Protect	Detect	Respond	Recover
Cyber Assistance	IT Asset Inventory, Vulnerability Assessment	Employee upskilling, Awareness Training, Encryption & Backup	Monitor, Alert Suspicious Information Flows, Block Payload	Forensics, Quarantine Infected Systems, Intelligence Cooperation (e.g., Extortion Consulting)	Data Restoration, Business Continuity, Review & Fix
Empirical Measures	Supply Chain Risk Management, End-of-life Systems Protection, Logging and Monitoring Protections	MFA, Patch Management, Email Filtering, RDP, Awareness Training, Backup	EDR, Logging and Monitoring Protections, Early Detection of Threats	Ransomware Incident Response Plan, Negotiation, Legal Consulting	End-of-life Systems Protection, Backup, PAM
Influencing Factors	Technical Vulnerabilities, Organizational Preparedness	Technical Vulnerabilities, Organizational Preparedness	Organizational Preparedness	Breadth of Impacted Entities, Duration of Incident Resolution	Technical Vulnerabilities, Breadth of Impacted Entities

Table 1 represents a layered interaction model rather than a static mapping of controls. Within each NIST function, cyber insurance services complement internal cybersecurity capabilities by extending organizational resources, while socio-technical factors condition the effectiveness of both. As a result, mitigation mechanisms are context-dependent rather than universally effective. For example, vulnerability assessments in the Identify phase are more effective in organizations with higher preparedness, and incident response coordination in the Respond stage produces greater loss reduction when organizational processes enable rapid decision-making.

In summary, these integrated activities illustrate how NIST-aligned security functions and insurance-enabled services can operate as a unified defense structure rather than as separate or sequential mechanisms.

3.3 Analytical Representation of the Mitigation Framework

To formalize the relationships illustrated in the framework, ransomware impact is modeled as a function of socio-technical risk drivers and mitigation mechanisms. Let the expected ransomware loss for organization *i* be represented as:

$$Loss = f(RiskDriver\_i, Mitigation\_i)$$

where *RiskDrivers* represents organizational conditions such as preparedness, technological posture, settlement duration, and network exposure, and *Mitigation* represents the combined effect of cybersecurity governance controls and insurance-supported services.

Mitigation consists of cyber risk controls embedded the NIST framework and insurance-supported mitigation services. It is not treated as a single aggregated input but as a structured combination of interacting components:

$$Mitigation = g(NISTControls, InsuranceServices, RiskDrivers)$$

Where *NISTControls* denotes internal cybersecurity controls aligned with NIST functions, and *InsuranceServices* represents external mitigation services from cyber insurance. The inclusion of *RiskDrivers* within the mitigation function reflects the context-dependent nature of mitigation effectiveness, indicating that the same mitigation strategy may have different outcomes across organizational environments.

This formulation implies two key points. First, mitigation exhibits a complementary effect, where the marginal effectiveness of cybersecurity controls increases in the presence of insurance-supported services. Second, mitigation is conditional, which means socio-technical factors moderate the relationship between mitigation measures and ransomware outcomes. For instance, organizations with higher preparedness may benefit more from incident response services, while highly exposed networks may reduce the effectiveness of detection mechanisms.

Together, these relationships define a non-linear mitigation structure in which ransomware loss reduction depends on both the interaction between mitigation components and the organizational context in which they are deployed. This analytical representation provides a formal foundation for the simulation model developed in the upcoming section. This structure differs from previous models that assume additive mitigation effects by explicitly incorporating interaction terms between governance controls and insurance services.

4. Research Design

To evaluate the effectiveness of ransomware mitigation strategies, this study adopts a quantitative test based on scenario-based simulation. The purpose of this approach is to test conceptual modeling while addressing limitations in publicly available ransomware datasets. Public cyber incident datasets typically provide detailed information about attack vectors, affected sectors, and incident characteristics, but they rarely capture the full range of mitigation services associated with cyber insurance or coordinated incident response efforts. As a result, relying exclusively on observed data may not fully capture the interaction between cybersecurity governance mechanisms and insurance-supported mitigation services. To address this limitation, a Monte Carlo simulation is implemented to examine how different mitigation configurations influence ransomware outcomes across organizational environments. This approach enables the study to evaluate both the direct effects of mitigation mechanisms and the conditional effects shaped by socio-technical risk drivers, providing a structured empirical basis for assessing the integrated mitigation framework proposed in Section 3. The simulation is designed as a theory-consistent evaluation rather than a predictive empirical model.

4.1 Simulation Method

To ensure reproducibility, the key socio-technical variables are operationalized as follows. Organizational preparedness is modeled as a continuous variable in the range [0,1], representing the maturity of governance structures, incident response planning, and security awareness. Technology posture represents the robustness of technical infrastructure (e.g., patching, system hardening), which is normalized to [0,1]. Network exposure reflects the degree of external connectivity and third-party dependencies, between 0 and 1, where higher values indicate greater exposure to propagation risk. Settlement duration is a positive continuous variable representing the time required to resolve ransomware incidents. These variables are treated as stochastic inputs in the simulation and jointly determine both baseline risk and mitigation effectiveness.

Two categories of mitigation mechanisms are incorporated into the model.

- CSF functions which represent internal organizational cybersecurity capabilities.
- Insurance-supported mitigation services, such as vulnerability assessments, digital forensics support, incident response coordination, recovery assistance. These services represent external resources that complement internal cybersecurity capabilities.

We identify the dependent variable as Ransomware Impact.

Ransomware impact represents the severity of consequences experienced by an organization following a ransomware attack. Because financial loss data are often incomplete in public disclosures, a composite impact indicator can be constructed based on observable incident outcomes. The ransomware impact variable may include indicators such as operational disruption duration, extent of system compromise, data exfiltration occurrence, recovery complexity. In analytical terms, ransomware impact can be represented as a continuous severity measure or as a categorical indicator of high-impact incidents.

A Monte Carlo simulation is used to generate a synthetic population of organizations with varying socio-technical characteristics. In the simulation, socio-technical variables are generated from bounded probability distributions to reflect heterogeneous organizational environments. Specifically, preparedness and technology posture are drawn from Beta distributions to capture variability across organizations, while network exposure is modeled using a right-skewed distribution to reflect the prevalence of highly connected systems. Settlement duration is generated from a log-normal distribution to capture the heavy-tailed nature of incident resolution time. The simulation is conducted over 10000 iterations to ensure stability of the results. Parameter values are selected to reflect realistic ranges observed in previous cyber risk studies, while allowing sufficient variability to examine relative mitigation effects across different organizational contexts.

Consistent with Section 3's framework, ransomware impact is computed as a function of baseline risk adjusted by mitigation effectiveness. Mitigation effects are modeled as multiplicative reductions in expected loss, allowing for interaction between cybersecurity controls and insurance-supported services. This structure captures both independent and joint effects of mitigation mechanisms and enables evaluation of complementarity across scenarios.

4.2 Result Analysis

We use Monte Carlo simulation to generate numerical values for the variables that are hard to observe. The synthesized data is used to evaluate how mitigation mechanisms influence ransomware impact. We show an example of model-generated results indicating the effectiveness of mitigation measures across four socio-technical contexts. While the results are not from real-world estimates, they provide a theory-consistent illustration of relative mitigation effects under uncertainty and support the study's modeling contribution. We present a flexible framework that adapts as more ransomware incident data emerges, assisting future researchers in analyzing evolving ransomware risks and mitigation strategies.

Table 2: Simulation Results

	Overall Sample (Baseline)		Weak Organizations (low preparedness / weak technology / high exposure)		Strong Organizations (high preparedness / stronger technology / lower exposure)	
Scenario	**Expected Loss**	**Reduction vs. No Mitigation**	**Expected Loss**	**Reduction vs. No Mitigation**	**Expected Loss**	**Reduction vs. No Mitigation**
No Mitigation	411097	-	943115	-	97814	-
CSF	262423	36.2%	648933	31.2%	48374	50.5%
Insurance Service	282434	31.3%	675968	28.3%	58661	40.0%
Integrated	163269	60.3%	429098	54.5%	23768	75.7%

Table 2 shows mean expected losses over 10000 simulations and relative reductions versus baseline. These values, consistent with the model's expectations, highlight differences in mitigation effectiveness rather than precise estimates. The results reveal several important insights regarding the effectiveness of ransomware mitigation strategies across different organizational contexts. First, mitigation effectiveness is context-dependent rather than universal. The same mitigation strategies produce different outcomes depending on

organizational preparedness and technological capability. For example, organizations with weaker preparedness experience substantially higher baseline expected losses compared with stronger organizations, indicating that organizational conditions significantly influence ransomware risk exposure.

Second, integrated mitigation strategies outperform isolated approaches. While both the CSF–based controls and cyber insurance individually reduce expected losses, their combined implementation produces the largest reduction across all scenarios. In the overall sample, the integrated strategy reduces expected losses by approximately 60.3%, compared with 36.2% for NIST-only mitigation and 31.3% for insurance-only mitigation. This finding suggests that technical controls and financial risk transfer mechanisms function most effectively when implemented together.

Third, organizational strength enhances mitigation effectiveness. Under the integrated scenario, ransomware loss reductions are about 54.5% for weak and 75.7% for strong organizations, showing that stronger security and lower exposure improve mitigation investments effectively. This result supports the study's socio-technical perspective that mitigation outcomes depend on both mechanisms and the organizational environment.

To summarize, these results highlight the importance of embedding cyber insurance-supported measures into institutional mechanisms such as CSF to achieve more robust ransomware risk mitigation.

5. Implications

This study's findings have important implications for both ransomware risk management and cyber insurance practice. The simulation results indicate that ransomware mitigation is most effective when internal cybersecurity controls and insurance-supported services are implemented as complementary rather than independent mechanisms. The integrated mitigation scenario consistently produced the greatest reduction in expected ransomware losses across all organizational contexts, outperforming both NIST-only and insurance-only approaches. This suggests that ransomware resilience should be understood not as the product of a single control domain, but as the outcome of coordinated socio-technical and institutional defenses.

From a governance perspective, the results emphasize CSF's value as a structured foundation for ransomware preparedness, detection, response, and recovery. However, the findings also suggest that internal governance mechanisms alone may be insufficient, particularly for organizations with weak preparedness, limited technological maturity, and high exposure. In such contexts, external support provided through cyber insurance services can extend organizational capabilities by supplying specialized expertise in vulnerability assessment, incident response coordination, forensic investigation, legal support, and recovery planning. Accordingly, organizations should move beyond viewing cyber insurance solely as a financial backstop and instead treat it as an operational component of cyber resilience strategy. This interpretation supports the proposed framework in this study, which positions insurance-supported services embedded in NIST-aligned functions across the ransomware lifecycle.

For cyber insurance, the findings support its latest trends: shifting from risk mitigator to proactive monitor and advisor, as it merges with cybersecurity services. In the model, insurance cyber services contributed to reduced expected ransomware impact by improving response capacity, accelerating recovery, and reducing the operational severity of incidents. This implies that cyber insurance can add strategic value through service design, vendor coordination, incident preparedness, and pre- and post-incident resilience assistance. Insurers may benefit from structuring policies to more explicitly align risk assessment and service provision with recognized governance frameworks such as the CSF. Through this alignment, cyber insurance can contribute to reducing organizational losses by encouraging proactive risk prevention, strengthening organizations' cybersecurity capabilities, and mitigating the severity of cyber incidents.

This study contributes to the growing recognition that ransomware is a socio-technical risk requiring interdisciplinary solutions. The simulation results show that mitigation outcomes depend not only on the presence of technical controls but also on preparedness, infrastructure quality, exposure, and recovery conditions. This has policy relevance as regulators, industry groups, and cybersecurity standards bodies may wish to promote better coordination between organizational security governance and cyber insurance ecosystems. Such coordination could support more consistent expectations regarding minimum controls, incident reporting, vendor engagement, and recovery planning, particularly in sectors facing systemic ransomware risk.

Overall, the central implication of this study is that effective ransomware mitigation requires integration. Organizations, insurers, and cybersecurity experts should move beyond fragmented approaches and instead

adopt coordinated defense models that combine governance frameworks, operational capabilities, and insurance-supported services into a unified strategy for cyber resilience.

6. Conclusion

Ransomware is a major cyber threat causing operational and financial damage. While organizations use cybersecurity frameworks and cyber insurance separately, they often lack a coordinated resilience approach. This study proposes an integrated framework combining cybersecurity practices with NIST-aligned insurance services to mitigate ransomware across various organizations.

Using Monte Carlo simulation, the study examined how different mitigation strategies influence expected ransomware losses under various socio-technical conditions. The results reveal three key findings. First, mitigation effectiveness depends on context, with organizational preparedness, technological capability, and exposure levels significantly affecting losses. Second, integrated mitigation strategies outperform isolated approaches. While NIST-based controls and cyber insurance each reduce losses, their combined implementation produces the largest impact. Third, organizations with stronger preparedness and tech capabilities benefit more from mitigation efforts, underscoring the importance of organizational readiness.

The primary contribution of this study is methodological. The paper introduces a modeling framework that integrates socio-technical risk conditions, governance controls, and insurance-supported mitigation services into a unified analytical structure. By linking cybersecurity governance with cyber insurance services, the framework provides a systematic approach for analyzing how different mitigation strategies interact to influence ransomware outcomes. This approach contributes to the interdisciplinary research that views ransomware not only as a technical threat but also as a risk management challenge.

There are some limitations. The simulation results rely on synthesized data designed to illustrate relative mitigation effects rather than precise real-world loss estimates. As a result, the findings should be interpreted as analytical demonstrations rather than empirical predictions. Despite these limitations, the study provides a structured foundation for understanding how integrated mitigation strategies can improve ransomware resilience. The framework proposed in this study offers a step toward developing more comprehensive and adaptive strategies for managing ransomware risk in complex socio-technical environments.

Future research can extend this work by incorporating real ransomware incident datasets, sector-specific risk parameters, and longitudinal analysis of mitigation effectiveness. These directions would empirically test the proposed framework and further validated in practical cybersecurity environments.

Abstract: Our modern smart cities and societies are rapidly changing in all aspects. These entities can be described as digital, multidimensional hybrid entities, where everything is interconnected and where different technologies are used to acquire, transmit, exchange, process, use, and store information. We need to look at these multidimensional information and communication system entities in a new way. The information and data models we use, and their functionalities, require communication systems that consist of air-space-land-sea communication networks (ASGM), in which the different components work seamlessly together. These digital, multidimensional hybrid systems include several parts and functions, such as various digital platforms and their services; a range of technologies, including artificial intelligence (AI), machine learning (ML), and virtual reality (VR) solutions; blockchains; digital twins; quantum technologies (communication, cryptography, and computing); metaverse environments; and various data center functions. These environments also use the Large Language Model (LLM). Our new smart devices must be developed to adapt and operate in these environments, using the services they provide, and they must function regardless of time and place across all usage contexts, including extraterrestrial networks. Data center capabilities, MECs, and edge systems are also rapidly evolving due to emerging communication requirements. Quantum computing, cryptography, and communication, alongside ML, are becoming available, and their integration must be explored, as they introduce additional challenges for device design and functionality. We must ensure sufficiently low transmission and synchronization latencies so that physical and virtual environments can interact seamlessly without failures. In this article, we examine smart devices designed for future communication environments. These devices will utilize artificial intelligence, machine learning, and virtual reality to support the services of future smart societies across operational domains, including those beyond Earth. We also analyze cybersecurity threats to end-to-end services in different use cases and explore device-level functional enhancements.

Keywords: Smart devices, Artificial intelligence, Virtual reality, Quantum computing, Quantum cryptography

1. Introduction

The living environments of future smart societies form many multidimensional hybrid communication environments, where users may not be able to know or see what kind of communication systems they are using in their everyday services. It cannot be seen or known whether air-, satellite-, ground-, or maritime-based communication networks and services are being used, because everything is connected to everything, and the services in use may be located on other continents (Figure 1). Multiple service providers use the same telecommunications network resources, including telecom operators, as well as subcontractors and stakeholders. This means that the entire future telecommunications environment will be multidimensional from the sky to the bottom of the sea, with connections everywhere and interfaces to many information systems and networks simultaneously. This will all work automatically in the future (Ericsson, agentic AI) (Akash Takyar). Communication systems pass through multiple countries, and service providers also use different data center resources to provide their services from these countries. This also means that telecom operators and service providers may use different recommendations and standards to develop their networks and services in these different countries. People use services with different security levels from these telecom networks regardless of time and place, which poses many additional challenges for developers and designers of information security systems. People may use their one smart device in a variety of ways to access multiple services, even if these services have different security levels. This means that managing and monitoring these telecom networks and the services provided through them, as well as their users, is particularly challenging. These new operating environments also offer a lot of new opportunities for cyber attackers to attack our systems and services through multiple routes and different devices.

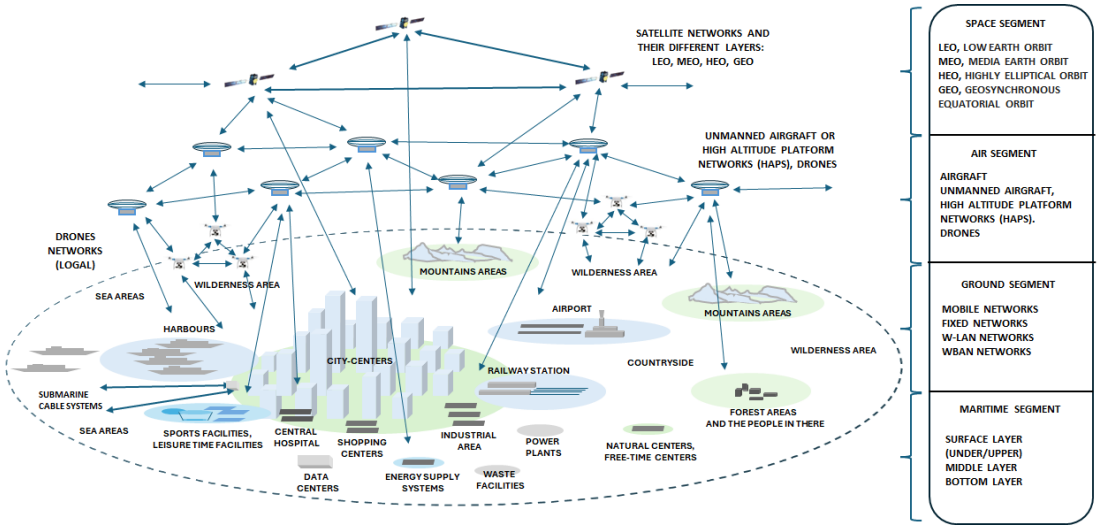

Figure 1: Our future societies' digital living environments and communications layers (EU-ECHO 2) (EU Space Programme) (IEEE, Oltjon Kodheli) (IEEE, Xufei Ding)

Artificial intelligence (AI) can be used in communication networks for many different purposes. It can be used to analyze information from data sources that we want to send to recipients through communication networks by performing multimodal data extraction on the sender side, encoding it, and decoding and reconstructing the data on the recipient side (Figure 2). Also, cyber attackers use AI in many ways to attempt to find vulnerabilities and attack opportunities from various parts of communication networks, their services and systems, and work environments, including all users' devices (EU-2024/1689) (EU-2022/640). As we evolve our digital communication and information environments through virtualization, slicing, and new virtual reality capabilities where everything is connected to everything, we are at the forefront of multidimensional communication and service environments. These different functionalities mean that the environment gives cyber attackers many more opportunities to attack these multifunctional environments than was previously possible for the networks of that time. These new functionalities in communication environments also mean that we need to take a deeper look at the devices and systems we use and to develop their architecture to meet these new requirements, functionalities, and cybersecurity challenges. Quantum computing, quantum cryptography, and quantum machine learning need to be researched and tested alongside these devices, as they are becoming integrated into this new generation of smart devices. We must strive to optimize the functionalities of new types of smart devices. Quantum computing, quantum cryptography, and machine learning must also be taken into account in new types of intelligent device architectures (IDQ) (ITU-T).

We need to optimize the functions of new types of smart devices, such as computing power, the use of artificial intelligence, the use of virtual reality, and energy efficiency. Since our smart devices provide a variety of services and are loaded with a lot of data, they are really loaded. We need to optimize and significantly reduce their load. One way to reduce the load is to form a semantic representation of the transmitted data and send it to an encoder, which encodes the data by optimizing its size; on the receiver side, the transmitted data is decoded and reconstructed accordingly. The goal of these processes is to optimize the load and improve the functions of these new types of smart devices in these new operating environments, Figures 2 and 3. Edge and MEC architectures and operations also need to be rethought due to the connectivity and cybersecurity requirements of these new types of smart devices and the new types of services they provide. These new types of end-to-end communication systems form the communication layers in these multidimensional (3D) environments where everything is interconnected to everything. This requires new types of analyses, control, and monitoring models and systems that can seamlessly analyze and manage data, prevent unauthorized access to data, prevent cyberattacks, and protect and keep our information systems operational under all conditions, end-to-end, across all communication environments. For these purposes, we use agent-based RAG concepts (Akash Takyar, Agentic RAG), which means that devices and systems can communicate with other systems and devices and react to their functionalities, adapting their behavior to be compatible with the various use cases of future digital environments and the various use cases of the systems there.

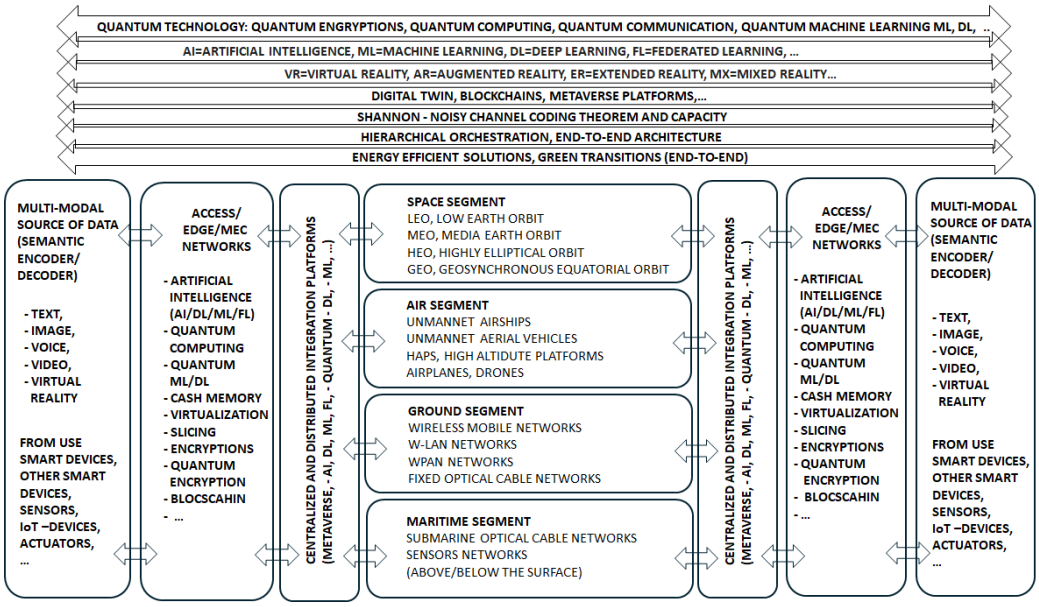

Figure 2: End-to-end communication segment layers and their functionalities

1.1 The Research Question

The research question of this study is: Can our new smart digital devices and systems be safely used in the multi-layered virtual environments of the future, where numerous services are available to us anytime and anywhere and artificial intelligence is used throughout our service and communication systems to enhance and improve our services?

2. Objective and Grouping of Paper

In this study, we use scenarios and use cases related to multimodal data in virtual reality and virtualized environments in different situations where collaborative information exchange with different people and parties is needed, and it needs to be done securely.

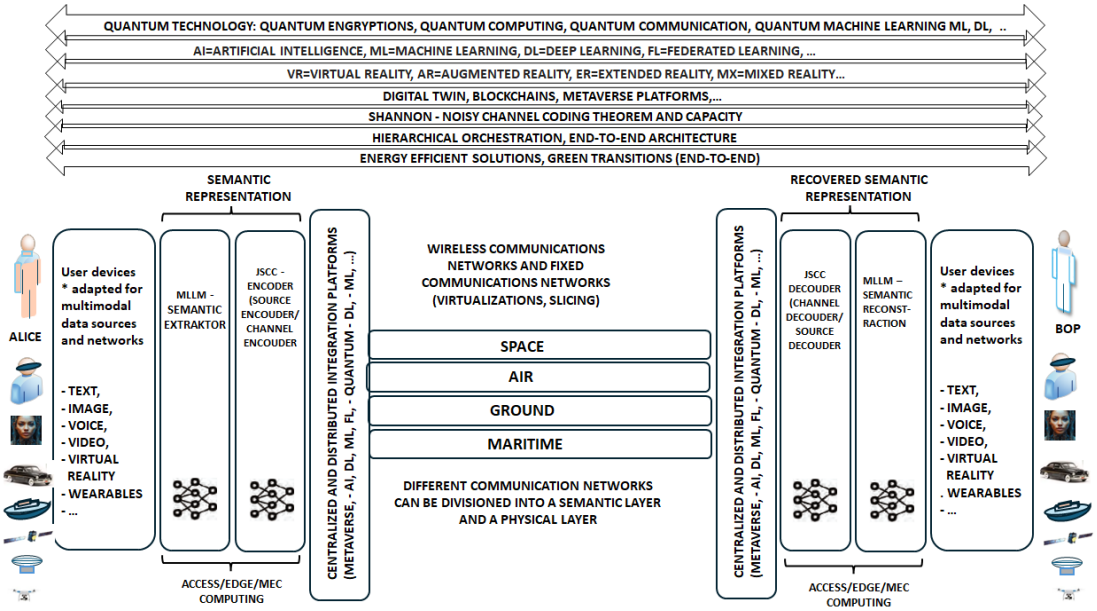

Figure 3: Secure MLLM semantic communications enabled Air-Space-Ground-Maritime networks, end-to-end, using AI agentic RAC and quantum technologies. MLLM (Multimodal Large Language Models) (IEEE, Huaifeng Shi) (IEEE, Mingkai Chen)

Methodology: We have used the Enterprise Architecture (EA) framework and its methodological models. We have also used Proof of Concept testing environments (Aarne Hummelholm et al. pp. 142–148) to identify the

improvement needs of the mobile devices people use. We also looked at the EU Tempest Directive guidelines to see what we need to also consider when designing our new device.

The structure of the study is as follows: Chapter 3 discusses numerous services that utilize virtual reality and different platforms in future societies in their multi-layered virtual and cloud-based digital environments, and the use of services is independent of time and place, even when service users are far from their workstations and offices. Chapter 4 discusses conducting threat analyses and modelling for these multi-layered platforms in virtual and cloud-based digital environments. Chapter 5 concludes this article, presents our solution model, and suggests future work.

3. Multimodal use Cases for Future Communication Environments at Different Levels

We use different technologies in communication environments across different segments. Multimodal data includes text, images, audio, video, virtual reality data, wearable data, IoT and sensor data, and so on. This multimodal data can include sensitive information from various fields, such as economic, industrial, medical, and welfare data; banking data; or technical development data. This data will be sent to various parts of the world using various communication systems (Figures 3, 4a, and 4b). The use of services in our future society's multi-layered virtual and cloud-based digital environments will be independent of time and location. Service users can be far from their offices and homes. Therefore, new types of smart devices are needed that include secure MLLM semantic communication functions, artificial intelligence-based agent-based RAC techniques, and quantum technologies.

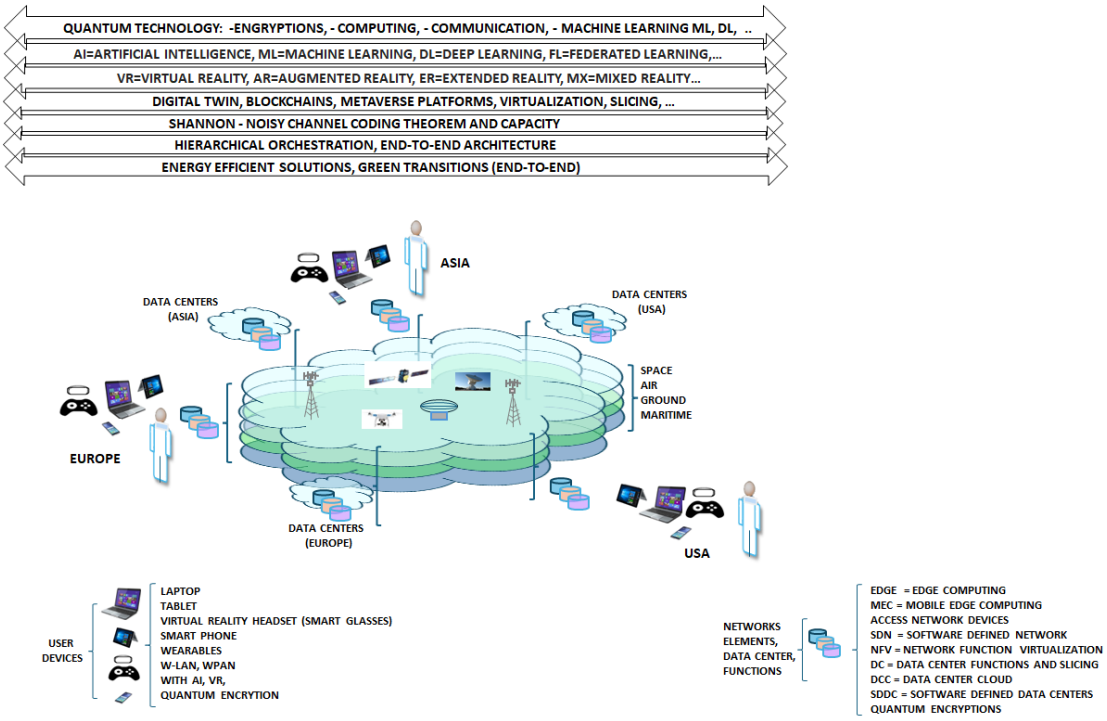

Figure 4a: A real-time business meeting with employees from around the world

We are also currently transitioning from 4G to 5G and 6G into mobile networks. This transformation brings with it technical challenges, as well as challenges related to privacy, accessibility, sustainability, and cybersecurity, but at the same time it opens revolutionary opportunities to develop services in our societies to be even more efficient, diverse, flexible, and energy efficient. For example, for various needs of rescue operations, we can easily introduce new types of mesh networks implemented with smart devices on an ad-hoc principle, without other networks. These solutions and new functions of the devices give us new opportunities and help us work much faster and easier in many situations. These new types of smart devices allow all of us to use services in a completely different way than before, and faster than today, regardless of time and place. Critical situations we do not need other networks and their services at all.

In Figure 4a, we see one example of the use of this new type of smart device, with its new functions, in meetings where people from companies are in various parts of the world (Nokia) (Ericsson). They can use a normal video conference connection with audio, video, and images. They also have virtual reality glasses that they can use,

but which are challenging to use due to delays in data transfer. The use of virtual reality glasses in meetings comes into play when the companies involved in the meeting are doing development work and the people from the companies want to see the results of their work up close. The connections used are complex and pass through different networks and countries (Figure 4a). The big challenge is that the inside information of the companies must not be available to parties outside the meetings and that hackers cannot access information. The connections must be encrypted, for example, with quantum encryption. This also increases data transfer delays. There may be many teleoperators and service providers who are responsible for making this type of connection through different countries using different communications networks. This gives more cybersecurity challenges to these types of connections.

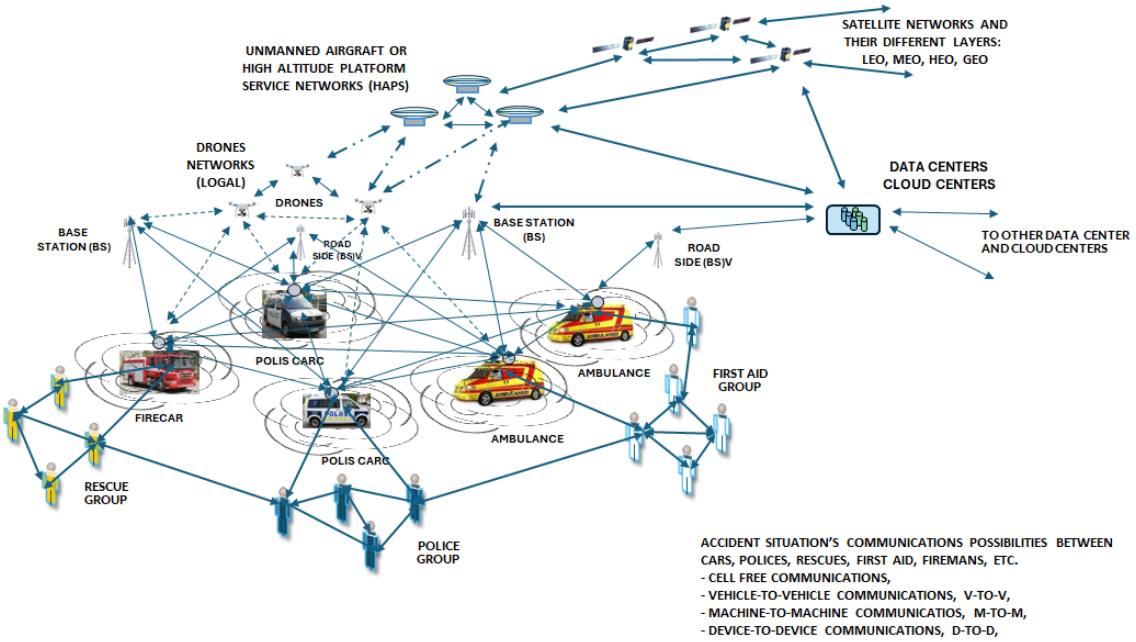

Figure 4b: A rescue operation in the field (Aarne Hummelholm et al., ECCWS 2025) (EU-NIS) (EU-GDPR) (EU-MDR) (EU-Galileo)

Figure 4b shows an example of the use of new types of smart devices that can form networks for rescue operations, for example, on an ad-hoc basis. The formed mesh networks operate without other networks, data centers, and their functions. The formed network is based on various functions of new types of smart devices (Aarne Hummelholm et al. p. 142-148). The mesh network is formed between user devices to user devices automatically without other networks when the necessary settings have been made in advance. If necessary, the network is connected to vehicles, which in turn are connected to each rescue operation command center and leader using various communication systems to get connections to the field (Figure 4b). Today, it is also possible to use direct connections from user devices to networks formed by satellite, HAPS and DRONE systems. Table 1 shows the technical requirements of different communication services in future service environments, which we need to consider when developing these systems and smart devices.

Table 1: Communication requirements for metaverse applications (Mansoor Ali)

Applications	Latency (ms)	Reliability (%)	Data Rate (Mbit/s)
Hologram Education (light field)	20	$1–10^{-5}$	$1x10^{5} – 1X10^{6}$
Augmented Reality Smart Healthcare	5	$1–10^{-5}$	10000
Digital Twin (Smart city)	5–10	$1–10^{-5}$	10
Virtual Reality Entertainment	7–15	$1–10^{-5}$	250
Tactile internet	1	$1–10^{-6}$	1

There are direct connections between the field managers from the beginning. Figures 4a and 4b show this in critical situations, where every second counts for initiating and conducting rescue operations. The faster and more seamless launch of the field operations shown in Figure 4b is enabled by configuring the communication

settings on user devices. We can certify all users in advance and profile them based on their job responsibilities. This way, they have certain operations ready when they go into the field, and their profiles are visible to all users on the screens of their smart devices. This means we do not have to make any changes in the field, and we are ready to start the necessary operations quickly.

4. Making and Modelling of Threat Analyses

Figure 5 shows connections between users in multimodal communication environments. User devices, communication systems, data systems, and platforms are virtualized. In this model, artificial intelligence is used in all areas of communication and in all devices and systems to analyze and optimize all communication connections and prevent cybersecurity attacks.

Our new smart devices are connected to a wide range of sensors, actuators, IoT devices, virtual reality devices, home systems and sensors, other user devices, wearable devices, etc. The connections are wireless or fixed. For example, at home many devices are connected to home WLAN (Wireless Local Area Network) devices and, through them, to EDGE (Network Edge Device) or MEC (Multi-access Edge Computing) devices, as well as to operator networks via fixed or wireless connections. In this way, the user's smart devices are connected to these digital, multidimensional hybrid networks and entities, which can be divided into several parts and functions as needed (Figure 5).

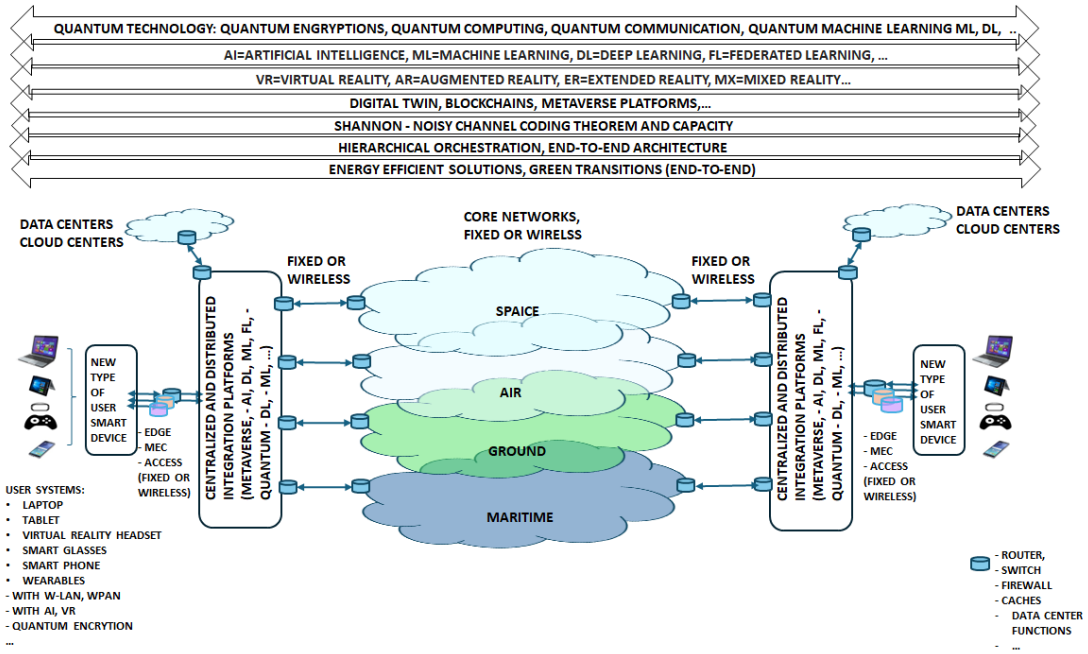

Figure 5: User-to-user communication connections in future multimodal environments

Some of these home systems are connected to the data centers of device suppliers via wireless or wired communication so that device suppliers can obtain information about the status and activities of home devices. Through all these connections and terminals, cyber attackers can attack our systems, even if our smart devices have encryption systems. This new environment offers cybercriminals, hackers, and state actors many new attack possibilities. The situation is only getting worse as they use different artificial intelligence (AI) concepts for their various attacks, as well as for vulnerability detection, dependency detection, detection of classified information, and so on in various parts of this multidimensional hybrid network. When we use wireless communication connections, cyber attackers use signal eavesdropping and interception methods. These methods have been used by state actors for a long time. Today, jamming is quite common among state actors around the world, including in Europe. Signal interception is used for many purposes, and users include state actors, cyber attackers, or criminals, etc. Through high-altitude communication systems, CPS spoofing and navigational deception are used quite frequently around the world through these communication routes. We have seen this from news reports on the international situation (IEEE, Miao Du) (Radware). State actors do it, and the purpose is to disrupt the normal operations of various states and companies. Wireless technologies offer the possibility of performing man-in-the-middle attacks on all wireless connections. Attacks against these wireless systems are easy to implement because they are difficult to detect if someone is doing something

alongside the connections. Side-channel attacks are also easy to perform in these environments. When state actors and cyber attackers use artificial intelligence and DRL (Deep Reinforcement Learning) (IEEE, Huaifeng Shi) to attack our systems, services, and system models, they can go faster inside our systems (Figures 1–5). Based on the information obtained, attackers perform more targeted attacks on our system models and try to find more backdoors for their attack possibilities.

Because we work in these multimodal communication environments and our communication connections go through multiple layers to data centers and cloud centers, cyber attackers and state actors can easily carry out eavesdropping and data leakage attacks to find the interesting information they want. When using artificial intelligence methods, they can easily conduct data manipulation attacks and privacy attacks. When cyber attackers and state actors use artificial intelligence methods, they easily find opportunities to conduct disruption attacks on their desired target. With the help of artificial intelligence, they find opportunities to get inside systems and devices and can easily conduct protocol attacks inside systems and devices. Finding such attacks is particularly challenging when we work in these multimodal communication environments and our communication connections go through multiple layers and paths to data centers and cloud centers, where services are potentially hosted by multiple service providers and where the information needed by users is stored.

The Access, MEC, and EDGE systems and devices of this future ASGM network must incorporate AI-based capabilities to detect, analyze, protect against, mitigate, and eliminate a wide range of cyberattacks. This is critical because all information flows through these systems and devices, as well as through users' smart devices, to networks and data centers around the world. If there is even one small vulnerability in these systems, cyber attackers will quickly find it using AI and quantum computing and exploit it for their own purposes. Figure 6 shows the attack vectors in our air-space-land-sea (ASGM) networks across its various segments and layers.

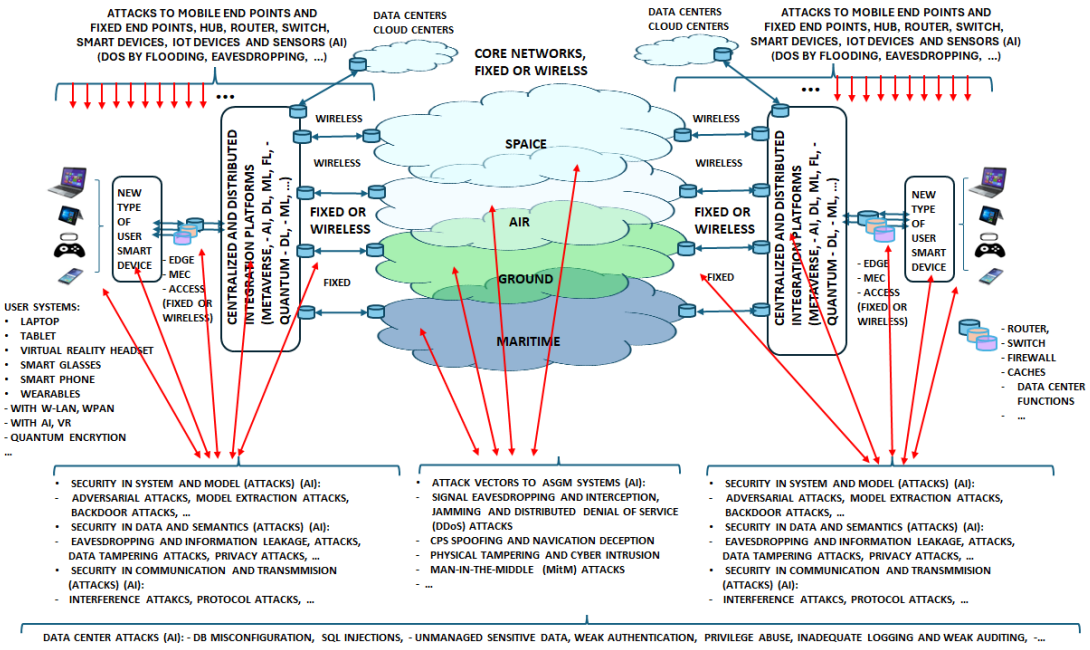

Figure 6: Our Air-Space-Land-Sea (ASGM) network and attack vectors against it (based on 5G threat vectors by Aarne Hummelholm et al.)

The management, control, and supervision of such multimodal and multilayered communication environments, user devices, communication systems, information systems and platforms, and cybersecurity-related protection systems in these virtualized and multilayered environments require good, functional analysis, control, and management systems for the network and its devices, as shown in Figure 7 as an example model (Aarne Hummelholm et al.). We need to get real-time information about our network situations and services and use artificial intelligence to create situational pictures faster and more broadly, to launch measures faster, and to collaborate to share information with different organizations working in these communication and service environments in their maintenance, servicing, analysis, and repair tasks.

Figure 7 shows two different operational centers: NOC and SOC. NOC is the network operational center, and SOC is the information security operational center. From the NOC, we see the real-time situation of the communication systems of networks and services, as well as the smart devices used. From the NOC, real-time information is sent to operators and service providers according to their needs. From the SOC, we see the real-time cybersecurity situation of networks and services, communication systems, and smart devices used. From there, real-time cybersecurity information is transmitted to various security organizations that are responsible for the activities of these areas in cybersecurity issues and respond to cyber-attacks as effectively as possible. For this reason, a real-time situational picture is important for initiating countermeasures, preventing cyber-attacks, and improving protection based on the analysis performed with AI.

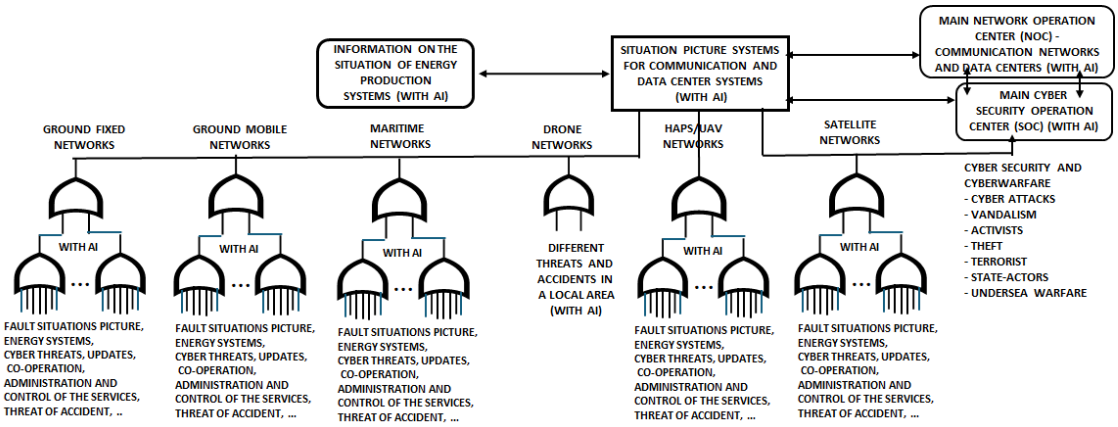

Figure 7: Architecture model of various network control and management systems at the principal level (NOC, SOC with AI and quantum computing) (Aarne Hummelholm et al., updated from the ECCWS 2025 article)

5. Our new Intelligent Smart Device Model

Figures 1–7 show how important and central the new smart terminals used by people are in these future digital multidimensional hybrid operating environments. A large part of the data flows passes through them, and various sensors, actuators, wearable devices, IoT devices, and other data sources are connected to them. Thanks to these functions, the device has become an increasingly central and important device that utilizes various services of future digital multidimensional hybrid operating environments and ICT operating environments.

Our new type of smart device includes functions that allow us to process data from incoming data streams (MLLM) and send the processed data to the recipient. The receiving device has corresponding functions for processing the incoming data. This method provides us with optimized data streams and energy-efficient data processing solutions on our smart device, as well as reducing the energy consumption of our smart device. We are also able to use these solutions to shorten the overall transfer times of data streams and improve the functionality of highly time-critical services.

Inside our smart device, we use artificial intelligence to analyze the device's functions and cyberattack potential, as well as to detect cyberattacks on our systems. We are developing these new smart devices with the use of quantum computing, quantum machine learning, quantum encryption systems, and EU-Tempest requirements in mind.

We plan to use Agentic AI to transform RAN optimization by enabling fully autonomous networks that manage themselves without human input (Ericsson, Agentic AI), so we need much deeper and faster AI-based analysis solutions to find out if something is going on inside the devices without our knowledge, even if it is not cyber attackers.

We also plan to use MCP (Model Context Protocol) in conjunction with LLM (Large Language Models) to provide a universal interface for reading files, executing functions, and managing contextual prompts on our new smart device.

One application of our new smart device is also the use of Agentic RAG functions, which improve the search and additional text creation process and enhance the use of MLLM models.

6. Conclusion and Future Work

6.1 Conclusion

The digital, multidimensional, and multimodal hybrid information systems of the future, where everything is interconnected and where different technologies are used to acquire, exchange, process, use, and store information, are particularly challenging in terms of functionality, usability, and cybersecurity (Figures 1–7). The same communication and service environments simultaneously give resources to multiple telecom operators, service providers, and stakeholders.

Our communication environments are changing rapidly, moving from 4G to 5G and eventually 6G in wireless technology. Extraterrestrial networks and services are already directly accessible from our smart devices. Our services are provided by multiple data centers and cloud service centers around the world. Such data environments offer attackers using artificial intelligence technologies a vast number of exploitable opportunities to attack our information systems and services from anywhere and at any time. Such future scenarios show us cybersecurity challenges that we must address with increasingly powerful analysis and protection tools to keep our systems and data safe from cyber attackers.

6.2 Future Work

We need to develop a testbed with robust integration platforms where we can evaluate, analyze, and validate our devices, systems, services, new protocols, and new quantum encryption systems much deeper used in these environments than before. We also need to test the use of artificial intelligence in conjunction with them because cyber attackers are using AI in their attacks in quite new ways. We need to evaluate and verify the use of quantum encryption systems in end-to-end mobile networks in such multidimensional hybrid computing environments (ENISA).

One of our research projects is to develop a secure new communication platform for our future smart devices, which will allow us to reduce the bandwidth requirements of data flows by modifying the information coming to smart devices through our new platform. After processing, the data is sent to communication networks (Table 1). At the same time, we will get energy efficiency solutions for our smart devices.

If we move to agent-based AI, it will revolutionize RAN optimization by enabling fully autonomous networks that manage themselves without human intervention. This means that we need to consider this possibility in the development of our future smart devices as well.

Ethical clearance: Ethical clearance was not required for the research.

AI declaration: I have not used AI in my work.

On Definition of Vulnerability Discovery

Simo Huopio and Erno Pasanen
Finnish Defence Research Agency, Riihimäki, Finland

simo.huopio@mil.fi
erno.pasanen@mil.fi

Abstract: The adaptation and exploitation of security vulnerabilities in military operations is a complex, multidisciplinary problem that calls for precise foundational definitions. This paper establishes such groundwork by discussing the principal elements of the topic from the perspective of security vulnerability research. We first characterize the sources and details of vulnerability and weakness information, describe common collection and presentation practices, and identify the principal consumers of this data. Next, we distinguish between vulnerability research and vulnerability discovery, explaining the processes that generate vulnerability information and highlighting the subtle but important differences between these activities. Finally, we examine principles governing the operational use of the vulnerabilities in military context and assess the respective contributions of research and discovery to achieving operational objectives. Within cyber domain operational planning we elaborate on (principle of) non-forceability. The primary hypothesis of non-forceability is that in cyber domain an adversary cannot induce an adverse effect on the logical components of a target system without proof of an exploitable logical vulnerability. This claim requires a precise explanation of the logical part of a system, which we define to include software, data, configurations, and formally defined user procedures and training; it explicitly excludes underlying processing platforms (hardware) and human actors (users and administrators). Under these definitions, external adverse effects on the logical system necessarily imply the proof of a vulnerability. Finally, the role of proof-of-concept (PoC) code in the operational utilization of software vulnerabilities has to be elaborated. We argue that the utility of vulnerability information is highly related on intended use and the level of technical detail provided. For defensive purposes, identification of a vulnerable component and its triggering mechanism is typically sufficient to trigger defensive actions. By contrast offensive operations require validation of adversaries' defensive capabilities before PoC code baseline capabilities, further development objectives and possible actions of objectives (impact) can be evaluated as an operational course of action.

Keywords: Vulnerability discovery, Vulnerability research, Cyber operations, Vulnerability exploitation, Proof of concept code

1. Background

Vulnerability discovery is a process of acquiring the technical knowledge of the existence and technical details of exploitable vulnerability on a target system. It is an enabler of cyber operations, which are systematic and planned actions that either are used to actively protect own systems by patching vulnerabilities and using security controls or leverage and exploit one or more of vulnerabilities of the target system in order to reach the overall operational goals.

The difference from the operations in physical domain is that if the target is properly protected in cyber domain, the defences cannot be forced even with significant superiority within the same domain. The exceptions to this logic are the human and physical elements of the protection, which deliver the effect outside the cyber domain. *Within the cyber domain, external actor cannot have any adverse effect to a logical part of the target system without knowing exploitable logical vulnerability.*

Non-technical security vulnerabilities in target system can be considered to have an effect in the logical world of cyber domain. As an example, inadequate security related routines of cyber system workforce are a security vulnerability if they enable the possibility of adversarial impact. Furthermore, even as the logical world of cyber domain is built on physical things there usually exists a possibility for the adversary to circumvent the elements of physical protection and humans with force superiority. For example, breaking physical barriers and forcing the human operators to violate the given security policy. These categories of vulnerabilities are not addressed in this paper.

2. Vulnerability information

2.1 Definitions Regarding Vulnerabilities

Dictionaries categorize *vulnerability* as an object either open to attack or damage ('vulnerable', 2024a) or being able to be easily hurt, influenced or attacked ('vulnerable', 2024a). According to MITRE (2025a), a vulnerability is an instance of one or more weaknesses in a system, that can be exploited, causing a negative impact to confidentiality, integrity, or availability. *Therefore, a security vulnerability is an exploitable weakness that circumvents security controls and is shown to have a negative effect when exploited.*

A (security) *weakness* is a condition in a software, firmware, hardware, or service component that, under specific circumstances, could contribute to the introduction of vulnerabilities (MITRE 2024a) by allowing the violation of an explicit or implicit security policy (MITRE 2024b). The conditions are usually called bugs, errors or flaws, and commonly used interchangeably regarding different severities; As an example, a typo can be called a bug, a logic mistake in code an error, and deeper mistake in software logic a flaw. Weakness is a specific class of error or flaw which turns to a vulnerability when instantiated in a system. Most common weaknesses are referred in *Common Weakness Enumeration (CWE)* -database (MITRE 2024c), a community-developed list of weaknesses maintained by MITRE.

There are many public vulnerability databases (Kekül, H, Ergen, B, and Arslan H, 2022) that provide *vulnerability descriptions*. NIST maintains one of the largest public databases, NVD (National Vulnerability Database) (NIST 2019). The vulnerabilities listed in these kinds of databases include typically *CVE (Common Vulnerabilities and Exposures) record* information. The CVE Record, issued by *CVE Numbering Authorities (CNAs)*, include the CVE ID, brief description of the vulnerability and number of references to vulnerability reports and advisories. Typically, the description includes also codified rating *The Common Vulnerability Scoring System (CVSS)*, which is created to help the software vendors and users comparing the severity of the vulnerability.

Proof of Concept (PoC) code is package of information with which one can reproduce the vulnerability on the targeted system, for example scripts, source code, or e.g. instructions for manipulating an user interface. The PoC should provide ways to validate triggering of vulnerability, for example information on specific error message or memory and register values that can be validated with a debugger. A PoC code covers typically a single vulnerability or a chain of vulnerabilities and generally does not impact the system otherwise than showing that system is vulnerable.

An exploit (code) makes use of the vulnerability to produce an effect in the target system. The effect can be a denial of service (DoS) where functionality of the target system is fully or partially disabled or e.g., remote code execution (RCE) where it is possible to deliver and execute attacker defined code in the target system. Exploit codes incorporate usually an elaborate combination of techniques to evade security controls. It is common that an exploit code targeting a software running modern operating system uses exploitation of multiple vulnerabilities.

2.2 Discussion About Vulnerability Information

Many parties contribute to publicly available vulnerability data. A large portion of it gets published by white hat (Shea, S. 2019) security research organizations. Vulnerability disclosures are typically preceded by a coordinated collaboration period with software vendors, often facilitated by one or more CERTs (Computer Emergency Response Team). During this period vendors can fix the vulnerability and prepare, test, and distribute the necessary updates which leads to end-users having patched systems when vulnerability is disclosed. This process is called "*Responsible Disclosure*" while some actors prefer "*Full Disclosure"* which includes releasing all the details to public without giving the software vendor any time to fix the bug beforehand. Some actors, like Google Project Zero, strike a kind of middle ground, giving a fixed 90-day period to fix the bugs, and 30-day period after the fix has been released before all details are released.

Vulnerabilities are also categorised by how long time has passed since the software vendor has acquired the knowledge of the vulnerability; *a zero-day vulnerability* means that vendor learns at time of disclosure. The vulnerabilities which have been fixed and the patch is not widely applied are called *one-day vulnerabilities*. To emphasise time passage since vulnerability disclosure (patched or not) term *n-day vulnerability* is used.

Information about most of the vulnerabilities end up to the public domain through security mailing lists (seclists.org. 2024) like Full Disclosure (Seclists.org. 2026), or a national CERT vulnerability mailing list (NCSC-FI. 2025), with posts linking to the researcher or software vendor blog giving more details about the vulnerability and ways to update.

2.3 Vulnerability Information - Conclusions

Vulnerabilities are different from regular software bugs because they have the potential to endanger the security of a system and its data. Cyber security researchers see this as a business opportunity, striving to claim CVEs for finding new vulnerabilities, branding bugs and creating security solutions to protect against malicious activities and reduce risks. However, as vulnerability information is consumed its usefulness varies between defensive and offensive scopes.

For the defender the vulnerability information has typically enough significance to trigger immediate action even without a patch or PoC information. Assessing the significance to own systems and setting up pre-emptive security controls (mitigations) can start before available patch. Vulnerability management process promotes a defensive approach to potential system risks requiring technical measures that mitigate threats even when detailed vulnerability information is unavailable. Such actions demand domain-specific and system-level expertise, for example in isolating management interfaces from adjacent networks.

For the attacker, a vulnerability information without a working PoC code does not yet have a significant value for the attacker. Even if PoC code is publicly available, it does not mean that anyone can exploit the vulnerability or that the vulnerability can be exploited with desired impact. Nevertheless, using PoC as a starting point for exploit development is easier than starting with just vulnerability description in typical CVE entry. (Shimizu, N. and Hashimoto, M 2026) For example, a vulnerability described just as occasional random changes in target application resources does not offer a lot to build an exploit on; without an exact method to trigger the vulnerability and information on how to control the changes on target the vulnerability remains without direct value. Alternatively, if there would be details on the weakness behind the vulnerability and at least one concrete way to control it, the starting points for exploit development is clear, and there is also a data to evaluate other related tactics, techniques, and procedures (TTP) for the attack (MITRE 2025b).

In conclusion, PoCs in a defensive context help build and validate existing mitigations and strengthen overall system security. In contrast, offensive use demands more detailed vulnerability information, as exploits must align with operational objectives and typically require additional research and development.

3. Security Vulnerability Research and Discovery

3.1 Definitions

Vulnerability research (VR) is a holistic research activity done by academic, commercial or governmental actors which aims for acquiring best available knowledge regarding vulnerability discovery tools and -methods. As sources research actors use public and academic sources, free and commercial trainings and possibly subcontracted research. Scientific method is used where applicable and research results are shared with research community for peer review and feedback. Therefore, found methods and built tools are available to parties doing vulnerability discovery and discovered methodologies and insights are available to other vulnerability researchers.

Vulnerability discovery (VD) is the act of searching for vulnerabilities from the applications, platforms and embedded systems of interest by applying the best public and commercial tools and methods available. The motivations behind the activity vary from actor to another; finding bugs from your own products (software vendors), finding bugs from the products you use (end users), making the internet safer place (white hat actors), earning money (bug bounty participants, vulnerability brokers), or getting enablers for your offensive operations (penetration testers, governmental actors, criminals).

Target setting for vulnerability discovery activity depend on customer; While needs of an offensive cyber operation can be very specific (“application of certain version”), the participants of a bug bounty programs have targets specified by the software vendors (“newest version of our product”), some white hack actors and criminal actors target everything their skills enable, selecting perhaps targets by potential impact of the findings (“All internet-facing popular applications”).

The vulnerability discovery can be divided in following phases:

- Open-source information gathering: Establishing the vulnerability history and current status of the target from partners and open sources.
- Analysis of the assumed usage the target. This can be enriched with existing threat emulation information.
- Architecture and software bill of materials (SBOM) analysis of the target implementation. Especially if target is larger than a single executable binary.
- Static analysis of the source code if available.
- Dynamic analysis of the executable code and the system at large using fuzzers, symbolic execution, or tracing, capturing and modifying the communications and debuggers
- Triage findings to three categories: Exploitable, possibly exploitable and non-exploitable using error logs, debuggers, trace tools and disassemblers
- Reverse engineering and analysis of the found anomalies using same tools as in Triage

- Creating the proof-of-concept code for reliably triggering the vulnerability (for defensive use) or for showing that the vulnerability could be exploited (for offensive use).
- Iterating to new discovery cycle in order to reach closer to actual target
- Communicating the results with customers, including impact analysis

The flow of vulnerability discovery on an abstract system is visualised in following Figure 1 (below) depicting the iterative cycle of vulnerability discovery: First iteration is launched to analyse the protected public application programming interface (API). Second iteration exploits the interim results and internal API in order to reach the wanted results.

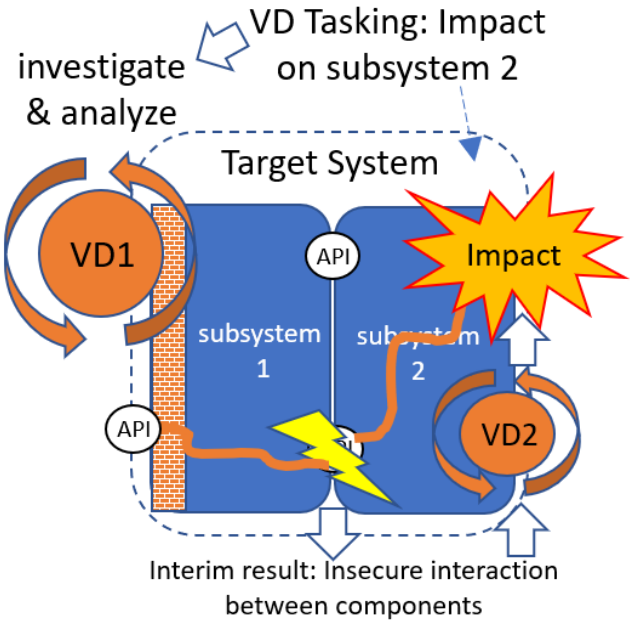

Figure 1: Example of iterative process of vulnerability discovery

Naturally not all vulnerability discovery processes follow all the listed phases; when testing own products during R&D you already have enough information to start static- and dynamic analysis, and no need for sophisticated PoC code to start fixing findings. Furthermore, the more complex and obfuscated the system is the more starting information, iteration and time is needed to discover vulnerabilities, if even possible with current knowledge.

3.2 Discussion on Vulnerability Research and Discovery

In practice every system has exploitable vulnerabilities in its architecture, software, and configuration. Some of these vulnerabilities are remainders of activities in the system R&D, some are result of the customer configuring the system in the usage environment and making decisions regarding update practices. This can be discussed and communicated with a single concept of security debt (Huopio, S. 2020), high amount of it means higher risk of having to pay it later in forms of security incidents.

Changes in the system configuration, operating environment or its functionality are common sources of new vulnerabilities. Because of this, the larger changes of architecture, and especially addition of new type of functionality have to be thoroughly analysed; New additions can for example expose old interfaces to new network segments, or introduce altogether new interfaces to access the system.

In order to have a credible cyber defence posture, a governmental user of critical heterogenous ICT infrastructure has to have an access to efficient vulnerability discovery capability. Usually, the system is so complex and multi-layered that relying just to the ability of the supply chain informing about software issues is not enough; *Objective for credible cyber defence posture has to be set on ability to do basic vulnerability discovery on all the relevant software platforms and embedded system types in own inventory.* (Goel, J.N. and Mehtre, B.M. 2015)

It is a good idea to start vulnerability discovery activities with a technical threat analysis workshop with help from vulnerability researchers and subject matter experts on related systems. Main objective of these workshops is to raise the technical vulnerability and risk knowledge of system/capability owner to a realistic

level subsequently prioritizing defensive activities according to defence-in-depth principles while gathering information for vulnerability discovery campaign. The workshop results can include: revised knowledge of the system use- and misuse cases, realistic threat environment and identification of critical paths and interfaces that could be used to disrupt the system.

The technical act of vulnerability discovery builds on top of results on the technical threat analysis workshop and involves a lot of manual work, interactive iterations of reviewing, choosing and applying tools and analysing the resulting system behaviour. It can be pursued in many abstraction levels; logical flaws can be found from analysing system architecture and (human or machine) interface thresholds or -networks, static analysis on source code and dynamic analysis of system essential binaries. The system can be tested with intentionally limited resources possibly revealing anomalies in less optimal resource conditions.

Results of vulnerability discovery are triaged in order to efficiently move forward with most likely (security) bug candidates. Dynamic analysis, especially fuzzing tools, can generate a lot of false positive results in form of vaguely anomalous behaviour which is typically hard to reproduce. With enough domain knowledge and proper use of automation, debuggers and tracing tools the analysts can extract the actual bugs out of the mass of data.

At this stage of process vulnerability discovery activities have typically produced at least some bugs with or without security impact. When working on defensive role, these findings can be brought to knowledge of the software vendor or in-house developer who can then proceed on fixing them. In this context *the key result of vulnerability discovery is the realistic hands-on knowledge of the weaknesses of the systems and the concrete own ability to assess the security posture.*

3.3 Conclusions

The threshold between vulnerability research and discovery is often blurred. While a target may seem easy to test initially and yield shallow bugs, advanced and experimental techniques might be needed to reach the deeper layers of the software logic and discover the deep bugs. Therefore, advancing on both routes are needed; getting systems under testing fast, and continuously researching more effective ways to discover vulnerabilities. Testing is always preferable to just speculating about potential vulnerabilities.

Vulnerability research is a comprehensive approach that is used to gather knowledge and to develop tools for broad applications, while vulnerability discovery applies those tools and insights to address specific issues. In this context, *vulnerability research is a holistic, exploratory process, whereas vulnerability discovery is a focused deterministic task.*

As time passes vulnerability research will continuously find new interfaces and approaches for vulnerability discovery to enhance defensive security posture: researchers bring new testing technologies and integrate and evaluate latest tools. Applying new methods and processes to unknown (Schumilo, S. et al. 2017) or known part of the system-under-test (SUT) can lead to surprising (Schumilo, S. et al. 2021) or even contested results (Nicolae, M. I., Eisele, M., & Zeller, A. 2023) and in a best-case scenario driving up the software quality by continuous testing and requirement crafting.

Ultimately, the primary distinction between vulnerability research and discovery lies in the intended target and its operational context, whether offensive or defensive. The less clearly defined the target, the more holistic the approach becomes, requiring broader research and information. A more targeted approach doesn't eliminate the need for research but instead directs it toward either expanding the attack surface or refining tool development.

4. Security Vulnerability Usage in Military Operations

4.1 Definitions

Cyber operation is a military operation executed in cyber domain. It can be of defensive or offensive nature, and has many separately defined subtypes (Scott, K.D. 2018). As discussed before vulnerabilities play a central role in all cyber operations as *all effects in cyber domain can be mapped as results of exploitation of a weakness or vulnerability*.

Operational context for using vulnerabilities therefore means that the existence of vulnerability is either a reason for executing protective actions in defensive operation or an enabler of one or more Course of Action (COA) proposals in an offensive military operation. The operational importance of the vulnerability is higher when PoC code or weaponised exploit code is available. A discovered vulnerability without apparent impactful

exploitation can be used as R&D starting point but if its usefulness is uncertain the cyber operation has to prepare for delays in execution and planning cycle.

Impact of exploited vulnerability can be defined as the desired effect (e.g. denial of service, remote execution, privilege escalation) and exploitation parameters (authentication needed/not needed, other environmental or version requirements for exploitation) in a specific part of the target system. In the operational context impacts description can be accompanied with additional parameters regarding the impact success probability, temporal factors (effects single transaction, certain time, or has permanent impact), or collateral impact description (Impact of system stability and non-targeted functionalities). The intended impact is partly shaped by the maturity of the exploit code. Although further R&D can enhance maturity, the inherent impact of a vulnerability is fixed by its underlying effects and cannot be changed. In context of military operational planning the impact of vulnerability should be used when planning for operational effect.

Payload is a piece of executable code or series of separate executable commands crafted to be used together for desired effect. Payload is provided to the vulnerability exploit code, which transfers it to the target system, prepares the environment so that the code can be executed, and triggers the payload code. It can be argued that in some cases part of exploit code can also be considered as payload, as it itself executes commands on target system. In the context of this paper, payload is defined as code specifically providing the planned effect for the operational target.

Vulnerability Equities Process (VEP) is a military process of making decisions on the usage of software vulnerabilities that are discovered or developed within own military organisation, or acquired from partners or subcontractors. By this definition the vulnerabilities that are of public domain are not considered in VEP.

4.2 Discussion

Vulnerability information is in central role in cyber operation planning, related decision making and in the actual execution both in defence an offence: when defending a system, the existence of vulnerable code in the system is critical information and causes immediate defensive actions of mitigation and patching. This information can be also gathered via preparation of battlefield; including vulnerable components in honeypots can lure attackers to reveal their attack capabilities and give the defenders information on how the vulnerabilities are being exploited.

In offensive operations vulnerability information is an enabler. Vulnerability discovery requires intelligence on target architecture, interfaces and specific software versions. Exploiting this information requires obtaining or developing suitable exploit code and maintaining the expertise to test and deploy it effectively. As the public vulnerability information is often lacking in the technical exploitation details, own vulnerability research and discovery capabilities are practically the only way forward. Preparing for almost unlimited variation on vulnerability discovery targets cannot be managed without capable vulnerability research supporting the vulnerability discovery team. The resource discussion is out of scope of this paper. What can be discussed is the approach in principle.

Offensive cyber operations imply a need for capability to develop proof of concept code for triggering and exploiting found vulnerabilities. It is worth noting that the knowledge of n-day vulnerabilities have also their worth; it is very common to discover outdated systems during reconnaissance. As vulnerability databases do not usually host exploit code with vulnerability details, exploit development is often needed also for n-day vulnerabilities.

The typical needs of offensive operations are targeted in a very specific way; vulnerabilities are needed for specific application or service, with a specific software version and specific operating environment. These kinds of tasks are hard and slow while outcome is very difficult or impossible to estimate. This type of activity requires additional information on adversary defence capabilities to allow targeting adversary weak spots while evading adversary. While the possibility of finding an exploitable bug in offensive operations timeframe is low, the impact of a new zero-day vulnerability would be high enough to justify the needed resources.

Another way of approaching offensive vulnerability discovery dilemma is to apply vulnerability discovery as “background” activity to large target space (for example, a Linux distribution). To maximise the yield and the probability of desired results in large scale the discovery tools should be used in necessary scale, parallelism and in an optimized computing infrastructure, as in OSS-FUZZ project (GitHub 2022). After a vulnerability is discovered a reverse search for target can be applied and operational planning can start with an initial COA.

In the larger context of cyber operation planning, especially in multi-domain operation (MDO) context, the potential external attack surface is much larger than just a single weakness, and typically more weaknesses need to be exploited after the initial access in order to reach the operational goal. As established earlier, there is a wide range of weakness types and each of them need different kind of approach for exploitation. One good reference of the exploitation techniques are the initial access and privilege escalation categories of MITRE ATT&CK knowledge base (MITRE 2025b).

While pure cyber operations have their place, especially on intelligence information gathering, many military operations are executed as multi-domain operations. ATT&CK lists some vulnerability exploitation methods that require physical access to parts of target system, e.g. by connecting an attacker-controlled hardware to the target system. These additional mission parameters help vulnerability discovery as it circumvents security boundaries through usage of other domains and provides more COAs.

In military cyber operations, vulnerability discovery is a key enabler of success. The ability to discover new exploitable vulnerabilities in a system of interest can used for both defensive and offensive gains. Therefore, in military cyber operations the vulnerability discovery should be exploited as supportive action whenever it is possible. In addition to own vulnerability discovery actions, access to non-public vulnerabilities and exploit code can be established.

Regardless of the source of new vulnerability information, the usage of specific vulnerability has to be decided in the context of operational needs. It is not outright certain that all vulnerabilities should be disclosed as they could be used offensively. This leads to discussion about Vulnerability Equities Process (VEP) (Vulnerability Equities Policy and Process for the US Government) (The White House 2017) which is out of scope of this paper.

Figure 2 illustrates the vulnerability-related data flows around security vulnerability research and discovery and security vulnerability usage in operations.

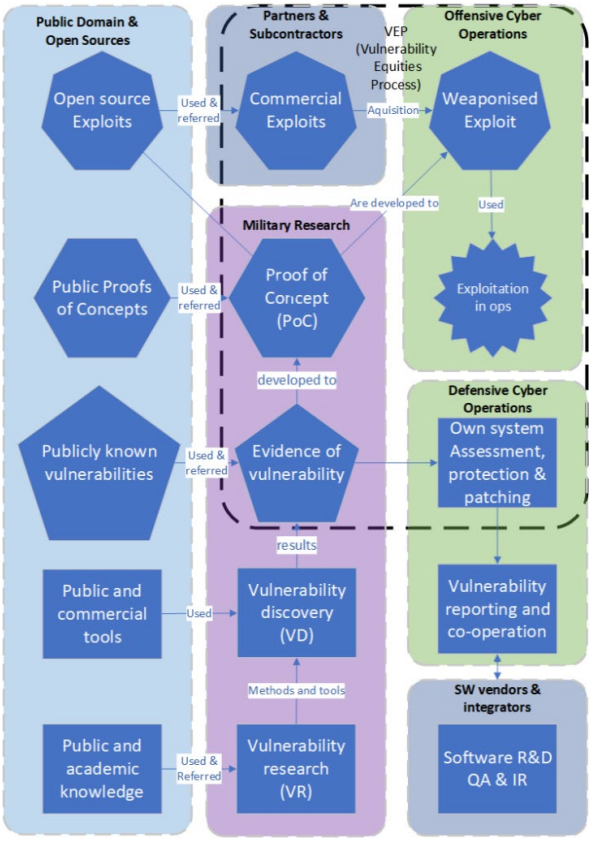

Figure 2: Vulnerability related data flows in military context

4.3 Conclusions

In cyber domain, all effects require a vulnerability on target system that is exploited. Without the technical knowledge of vulnerability and its exploitation and means to execute it, an operation cannot use it as a part to

reach its goal. For ability to plan and execute offensive cyber operations there has to be means to acquire vulnerabilities and related exploit code from open sources, through own vulnerability discovery or from other venues.

Vulnerability discovery is not inherently offensive or defensive. Even exploit code development is not offensive as such. Only when the exploit code is used to deliver a payload in order to make an impact is the act clearly offensive.

In an operational context, PoC code is used to define and validate the potential impacts of a vulnerability in offensive scenarios. The absence of PoC code can have collateral effects also in defensive operations: if the exploitation method is unclear, only mitigation can be applied, not full remediation. Some weaknesses can't be mitigated due to their context—critical system requirements may even prevent adequate mitigation. Therefore, even in defensive contexts, creating PoC is essential to guide both mitigation and remediation efforts. Thus, a PoC-code is required for both defensive and offensive operations to accurately assess the impact of a vulnerability.

Ethics declaration: Ethical clearance was not required for the research.

AI declaration: Outside of triggering now ubiquitous AI-assisted web searches, no other AI tools were used for the research.

Abstract: Wireless implantable medical devices (IMDs) have transformed clinical care but have also created a cyber-physical attack surface in which security failures can cause direct physiological harm. This tension is most acute in emergency access: clinicians must rapidly interrogate or reprogram devices under conditions that invalidate normal authentication. Security measures can delay critical care; mechanisms guaranteeing rapid access introduce vulnerabilities. This paper offers a critical review treating IMD emergency access as a safety-critical socio-technical exception regime, not merely a technical backdoor. We synthesise major access mechanisms—proximity triggers, break-glass credentials, external mediators, and manufacturer-mediated approaches—and analyse them through threat models, safety failure modes, human factors, and governance structures. We emphasise how cognitive load, workflow disruption, and long device lifecycles amplify risk during urgent interventions. The analysis shows that these mechanisms redistribute risk among patients, clinicians, manufacturers, and regulators, and that both security and safety failures can be catastrophic. We argue that no single mechanism can simultaneously maximise safety, security, and accountability across diverse contexts. We conclude by specifying the governance interventions required to make emergency access defensible in practice.

Keywords: Implantable medical devices, IMD, Emergency access, Cyber-physical security, Safety-critical systems, Break-glass mechanisms, Governance and risk redistribution

1. Introduction

Software-driven IMDs, such as pacemakers, ICDs, and neurostimulators, now rely heavily on wireless communication. This shift has improved therapy and follow-up care but has also expanded the cyber-physical attack surface in ways that directly affect patient safety (Halperin et al., 2008; James et al., 2025; Straw, Ashworth, and Radford, 2022). A central unresolved challenge is emergency access. In acute situations—malignant arrhythmias, device malfunctions, or therapy mis-delivery—clinicians may need to immediately stop, interrogate, or reprogram an ICD. Yet security controls designed to prevent unauthorised manipulation can delay these lifesaving interventions, while mechanisms that guarantee rapid access introduce new vulnerabilities (Denning et al., 2009; Tandon et al., 2024).

Early research demonstrated that assumptions about "security through proximity" or proprietary interfaces were insufficient, showing that unauthorised access was feasible under realistic conditions (Halperin et al., 2008). Finkle (2016) reports that cybersecurity researcher Jay Radcliffe has identified vulnerabilities in the Animas OneTouch Ping insulin pump that could allow an attacker to spoof wireless communications and trigger unauthorised insulin delivery. Innes (2019) also reports that Arizona clinicians have begun preparing for the possibility of cyberattacks on medical devices, highlighting the clinical implications of compromised pacemakers and other implantables. Subsequent work highlighted how IMD resource constraints, long lifecycles, and dependence on external programmers complicate the application of conventional cybersecurity controls (Denning et al., 2009; Marinescu et al., 2025). Schmitt and Alli (2020) argue that healthcare cybersecurity failures often stem from the application of generic security models in highly specialised clinical environments. More recent analyses broaden the threat landscape to include insider misuse, governance gaps, and lifecycle degradation across decades of deployment (James et al., 2025). Despite these findings, emergency access is still typically treated as a secondary feature embedded within broader security proposals, which has the practical effect of framing it as a security–usability optimisation problem rather than as a distinct safety-critical challenge.

This framing is inadequate. Evidence from digital health and human-factors research shows that emergency care occurs under extreme cognitive load, time pressure, and incomplete information, in which even well-designed controls can fail unpredictably (Tandon et al., 2024; Sendelbach and Funk, 2013; Bonney, 2011,

p. 240; Sutton et al., 2020). In these conditions, security failures (e.g., blocked access) and safety failures (e.g., misconfiguration) are clinically indistinguishable. Moreover, decisions about who may override an IMD in an emergency embed implicit assumptions about authority, responsibility, and acceptable harm. Governance research demonstrates that emergency access mechanisms redistribute risk among patients, clinicians, manufacturers, and regulators rather than eliminating it (Beckers et al., 2016; Ison et al., 2025; Díaz-Martínez et al., 2025).

This paper, therefore, treats emergency access not as a usability exception or a technical backdoor but as a socio-technical exception regime within a safety-critical cyber-physical system. By synthesising technical mechanisms, failure modes, realistic threat assumptions, and governance constraints, the review clarifies why no single mechanism can simultaneously maximise safety, security, and accountability across diverse clinical and regulatory contexts. Rather than proposing an optimal solution, the analysis identifies the structural tensions that shape emergency access and argues that governance and standards must drive future progress as much as device-level innovation.

2. Methodology

This review employs a critical narrative synthesis to evaluate the emergency access landscape for IMDs, integrating principles from technical security engineering, human factors research, and governance analysis. The methodology recognises emergency access as a sociotechnical exception within a regime in which technical performance is inseparable from human and environmental variables.

2.1 Search Strategy and Corpus Construction

A systematic search was conducted across Scopus and Google Scholar. The core search string targeted the intersection of IMDs, access control, emergency use, and security–safety concerns: (“implantable medical device” AND (“access control” OR “authentication”)) AND (“emergency” OR “break-glass”) AND (“security” OR “safety”). Supplementary searches incorporated device-specific terms (e.g., 'pacemaker', 'ICD', 'insulin pump'). The timeframe spanned 2008–2025 to reflect developments following Halperin et al.’s seminal work. The aim is to establish a baseline of IMD-specific security literature; the review intentionally draws on insights from adjacent domains. This inclusion compensates for the relative scarcity of empirical studies specifically addressing IMD-human-factors interactions in emergency scenarios by extrapolating established principles from digital health and safety-critical cyber-physical systems.

2.2 Analytical Framework: Thematic Coding

A qualitative thematic lens was applied to the corpus, focusing on how technical mechanisms interact with operational constraints. Rather than relying on singular experimental data, claims regarding clinical workflow and cognitive load are derived from cross-disciplinary thematic patterns:

Technical Constraints: Evaluation of mechanism feasibility based on IMD power and computational limits.

Human Performance: Extrapolation of error probabilities under stress from broader digital health studies.

Structural Tensions: Identification of irreducible trade-offs where security controls measurably increase time-to-intervention.

2.3 Evaluative Scope and Theoretical Deductions

As a critical perspective piece, this methodology does not claim exhaustive systematic coverage of all IMD security literature. Instead, it uses a socio-technical evaluation to identify structural tensions—such as the "security-safety inversion"—treating them as inherent properties of complex systems. Claims regarding clinical workflow disruption and the impact of cognitive load are presented as theoretically grounded deductions synthesised from technical constraints and human-factors principles. This approach moves the analysis beyond descriptive summary to specify the governance interventions required for defensible emergency access.

3. System Boundaries and Definitions

Clear system boundaries prevent conflation of technical, clinical, and governance challenges. This section defines the scope and key terms used throughout the analysis.

3.1 Implantable Medical Devices (IMDs)

Jeremy and Nicole (2010) define IMDS as devices that are permanently or semi-permanently implanted in a patient to treat an underlying medical condition. This category includes cardiac implants, neurostimulators, and implantable drug delivery systems. These devices share several defining characteristics: constrained computational and energy resources, reliance on external programmers or controllers, long operational lifetimes, and deployment within complex physiological environments (Maisel and Kohno, 2010; Marinescu et al., 2025). Wearable, external, or intermittently attached medical devices are explicitly excluded, even when they interface with implanted components. Although such systems raise important cybersecurity and usability concerns, their failure modes, consent assumptions, and access pathways differ fundamentally from those of permanently implanted devices. These exclusions ensure that the analysis remains grounded in the structural constraints of IMDs rather than drifting into speculative or non-implant contexts, where emergency access is based on fundamentally different assumptions.

3.2 Emergency Access

Emergency access in implantable medical devices can be understood as a set of capability-limited interaction pathways among the clinician, the device, and the supporting infrastructure operating under conditions of uncertainty and degraded assumptions. These pathways are instantiated through various concrete mechanisms—such as magnet responses, programmer-mediated sessions, or telemetry-driven alerts—that expose only a bounded subset of device functionality in ways that depend on device type, manufacturer-specific design, and clinical environment.

Let emergency access in implantable medical devices be represented as a family of time-critical, capability-limited interaction pathways:

$\prod = \{\pi_1, \pi_2, \ldots, \pi_n\}$

Each pathway $\pi \in \prod$ is characterised by:

$\varsigma \in \varsigma_{set}$: Triggering conditions, such as magnet placement, programmer invocation, or contextual inference based on physiological or environmental signals.

$\tau \in \mathbb{T}$: Access latency, defined as the time required to achieve a clinically meaningful action.

$s \in \mathbb{S}$: Scope of accessible functionality, capturing whether the pathway permits, for example, read-only interrogation, therapy suspension, or constrained reprogramming.

$\mathcal{R} \in \mathbb{R}$: Recoverability, understood as the ability to re-establish a safe and controlled system state following intervention under conditions of uncertainty and degraded assumptions.

Let B_N denote the behaviour set available during normal operation, and B_{AUX} denote auxiliary mechanism-specific behaviours (e.g., fixed-rate pacing under magnet application). Each emergency pathway π exposes a behaviour subset:

$B_\pi \subseteq B_N \cup B_{AUX}$

Emergency access analysis then focuses on the structure of $\prod$ and the distribution of (ς, $\mathbb{T}$, $\mathbb{S}$, $\mathbb{R}$) across devices, mechanisms, and clinical contexts.

Framing emergency access in terms of these pathways foregrounds access latency, functional scope, and recoverability as central design and governance dimensions and captures the heterogeneous, partial, and human-mediated nature of emergency interactions with implantable medical devices.

3.3 Security and Safety

'Security' refers to the protection of IMDs against unauthorised access, manipulation, or disruption, whether malicious or accidental. "Safety" refers to avoiding an unacceptable risk of physical harm to the patient that arises from device behaviour, malfunctions, or delayed interventions. In IMDs, these concepts are inseparable: a security control that delays access can directly cause physiological harm, while a safety-orientated override

can introduce exploitable vulnerabilities or pathways to misuse (Halperin et al., 2008). This review treats security and safety as coequal, interacting risk domains, rather than as independently optimisable objectives. To move beyond purely descriptive treatments, we formalised the security-to-safety relationship as a minimal, three-variable system. Let any emergency access mechanism be represented as a tuple:

$M = (S_1, S_2, S_3)$,

where:

S_1 (Security strength) denotes resistance to unauthorised access or manipulation.

S_2 (Safety responsiveness) denotes the time required to achieve successful clinical intervention, and

S_3 (Accountability clarity) denotes the degree to which actions are attributable, auditable, and reviewable.

Under this formulation, emergency access mechanisms can be compared not as discrete implementations but as positions within a constrained trade-off. Empirical and theoretical work across IMD systems suggests that these variables are not functionally independent. In particular, for all known mechanism classes, increasing S_1 beyond a certain threshold results in S_2 degradation under emergency conditions.

This formulation does not claim a strict mathematical optimality range; instead, it defines a testable system property: mechanisms that strengthen authentication, validation, or control layers beyond a given threshold introduce latency, complexity, or dependencies that measurably increase time-to-intervention. This model provides a basis for analysing emergency access as a constrained optimisation problem with clinically bounded tolerances rather than as a purely technical design challenge.

3.4 System Boundary Exclusions

To maintain analytical rigour and focus, this review explicitly excludes several domains: namely, artificial intelligence applications in diagnostic or control systems; population-scale, remote-only cyberattack scenarios lacking immediate physical or clinical consequences; the design or benchmarking of novel cryptographic protocols; and any empirical performance evaluation of specific commercial devices beyond established case studies. These deliberate exclusions focus the paper's findings on the fundamental structural and governance challenges inherent in securing emergency access to medical technology, rather than diverting attention to speculative technological solutions or complex engineering details.

3.5 Stakeholders and Responsibility

Emergency access mechanisms inherently redistribute risk and responsibility among patients, clinicians, manufacturers, and regulators, not because clinical roles or training differ, but because each mechanism embeds implicit assumptions about who is trusted and what actions are permissible. For example, a proximity-triggered override implicitly assigns risk to the patient by treating anyone physically close to them as an authorised actor. Governance and socio-technical systems research shows that such redistributions are a structural property of safety-critical systems rather than a consequence of any particular design choice (Beckers et al., 2016; Ison et al., 2025). Making these allocations explicit provides the foundation for the taxonomies, threat models, and failure mode analyses that follow.

4. Issues in the Technical Foundations for IMD Security

The design and evaluation of any emergency access mechanism for IMDS must be grounded in an understanding of its inherent technical constraints and the cryptographic primitives available to engineers. These factors fundamentally bound the solution space and defined the core security-safety tension.

4.1 The Primacy of Resource Constraints

IMDs are examples of systems that have very few resources. Their defining characteristics—miniaturisation, a non-replaceable battery lifespan of 5–15 years, and limited computational power and memory—create a design paradigm where security cannot be an afterthought but must be meticulously balanced with device longevity and core therapeutic functions. Traditional, resource-intensive cryptographic operations, such as standard asymmetric encryption methods like RSA, are often prohibitively power- and computation-intensive for direct implementation on the implant itself (Samaraweera et al., 2025). Consequently, a robust security scheme incorporating authentication, encryption, and authorisation may not be feasible if it significantly degrades battery life or delays life-critical operations (Camara, Peris-Lopez, & Tapiador, 2015). This limitation is

not merely an engineering challenge but also a direct security vulnerability; adversaries can exploit power-hungry protocols to launch Denial-of-Service (DoS) attacks that rapidly deplete the IMD's battery.

4.2 Evolution of Cryptographic Strategies for IMDs

In response to these constraints, the field has evolved from non-existent or weak security to a suite of lightweight, context-aware cryptographic strategies. Research has moved beyond simple, static keys toward more dynamic and resilient foundations:

Lightweight Cryptography: The imperative is for "lightweight security mechanisms" tailored for devices (Sun, Lo and Lo, 2017). This includes optimised implementations of standards such as the Low-Power Advanced Encryption Standard (AES) for Implantable Cardiac Devices and the use of elliptic-curve cryptography (ECC), which offers stronger security per bit than RSA, making it more suitable for constrained environments (Liu, Richardson, and Van der Spiegel, 2021).

Physiological Key Generation: A significant innovation is the use of the patient's own body as a source of security. By deriving cryptographic keys from unique, time-variant physiological signals such as the electrocardiogram (ECG) or photo-plethysmogram (PPG), these schemes enable secure access without pre-shared secrets (Karimian et al., 2017; Rahimi M.S., 2021). Techniques such as fuzzy vault and fuzzy commitment are employed to handle natural signal variability, allowing a legitimate programmer in proximity to generate the same key as the IMD for authentication and session establishment.

Proximity and Context as Security Parameters: Cryptographic protocols are increasingly integrated with physical and contextual safeguards. Distance-bounding protocols measure the signal's time of flight to verify that a programmer is physically near the patient, thereby mitigating relay or man-in-the-middle attacks (Camara, Peris-Lopez and Tapiador, 2015; Tabassum et. al., 2018). Furthermore, the concept of "context-aware security modes" proposes dynamically adjusting security postures – for example, relaxing authentication in a verified emergency room setting, which requires cryptographic systems that can support such policy shifts (Riegler, Sametinger, and Rozenblit, 2022).

These technical constraints explain why 'ideal' security solutions are impractical and why the trade-offs that follow are structural, not merely design choices

5. Emergency Access Mechanism Taxonomy

This section classifies emergency access mechanisms by their trust anchors and operational assumptions, following recent research on cyber-physical systems and governance (Beckers et al., 2016).

5.1 Physical Proximity-Based Mechanisms

Physical proximity mechanisms enable emergency access by allowing interaction with the implanted device from a short distance, typically via magnets, inductive coupling, or short-range electromagnetic triggers. Activation places the device into a predefined emergency mode, such as therapy suspension or simplified programming access. These mechanisms rely on physical presence as the primary trust anchor, implicitly assuming that those in close proximity during emergencies are authorised clinicians. Their principal advantages are minimal latency and independence from external infrastructure, which align with clinical urgency. However, recent analyses emphasise that proximity alone is a weak authorisation signal in crowded or uncontrolled environments, particularly given the severe consequences of accidental or unauthorised activation (Halperin et al., 2008; James et al., 2025).

5.2 Credential-based “Break-Glass” Access

Credential-based break-glass mechanisms permit emergency access when specific credentials, override codes, or emergency procedures are invoked. These mechanisms intentionally relax standard access controls under predefined emergency conditions, often accompanied by enhanced logging or post-event review. While this model preserves an explicit notion of authorisation, it also introduces vulnerabilities associated with credential availability, memorability under stress, and long-term exposure over the multi-decade lifetimes of IMDs. Human-factors research indicates that reliance on rarely used credentials during emergencies increases error probability and delays intervention, undermining safety objectives even when security controls function as designed (Denning et al., 2009; Tandon et al., 2024).

5.3 External Mediator Devices

External mediator approaches introduce an intermediary device, such as a programmer, shield, or policy-enforcing controller, that brokers emergency access between clinicians and the IMD. The mediator may authenticate users, enforce access policies, or temporarily relax constraints while maintaining an audit trail. This class delegates trust to the mediator, leveraging its greater computational capacity and flexibility relative to the implant itself. While such separation can reduce on-device complexity and attack surface, it introduces a dependence on the availability, integrity, and proper configuration of external devices, which may be absent or compromised in emergency settings. Cyber-physical systems research highlights that mediator failures often manifest as access denial rather than graceful degradation, amplifying safety risk (Marinescu et al., 2025).

5.4 Manufacturer-Mediated Emergency Access

Manufacturer-mediated mechanisms rely on device vendors to authorise or enable emergency access—possibly through proprietary tools, remote authentication, or emergency support channels. The manufacturer, acting as an external authority, centralises trust. While these methods can facilitate precise control and traceability, they also introduce latency, connectivity dependence, and jurisdictional complexity, which are ill-suited to acute clinical care. Recent governance-focused reviews indicate that manufacturer-mediated access introduces unresolved issues regarding liability, clinician autonomy, and equitable availability across healthcare systems (James et al., 2025).

5.5 Context-Conditioned Access Mechanisms

Context-conditioned mechanisms infer authority based on environmental or situational cues, such as location, time, or detected physiological distress. Access may be granted automatically or semi-automatically when predefined conditions are met. These mechanisms shift trust from explicit actors to contextual inference, reducing clinician burden but introducing risk from false positives and false negatives. Evidence from digital health and human-centred systems research suggests that contextual signals are often ambiguous or noisy during emergencies, making an incorrect inference a significant safety hazard rather than a marginal edge (Tandon et al., 2024).

5.6 Cross-cutting Taxonomic Dimensions

Emergency access mechanisms across different classes of connected devices, including implantable medical devices, are fundamentally characterised by four critical, interdependent dimensions: the trigger modality (how access is initiated, e.g., physical action, credential, or inferred context), the primary trust anchor (what establishes confidence in the access attempt, e.g., proximity, identity, or vendor authority), the degree of infrastructure dependence (whether the system operates locally or requires external network support), and the inherent reversibility and auditability of emergency actions. While technological configurations across these dimensions are numerous, a key finding from recent systems and governance research is that no single design eliminates risk; rather, each unique combination reallocates the inevitable risks associated with potential misuse or failure modes across various stakeholders, including patients, clinicians, manufacturers, and regulators.

5.7 Implications of the Taxonomy

This revised taxonomy underscores that emergency access mechanisms are not interchangeable technical options but embodiments of distinct assumptions about trust, urgency, and responsibility. By stabilising these categories before evaluation, the taxonomy provides a structured basis for the threat modelling and safety failure analyses that follow without implying that any single class offers a universally defensible solution.

6. Threat Modelling and Adversarial Assumptions

A realistic threat model for IMD emergency scenarios must extend beyond remote hacking. Consequential harm often stems from non-malicious failures and operational stress, not just adversarial sophistication (James et al., 2025). This section evaluates how these mechanisms fail under realistic adversarial and clinical conditions. Specifically, the critical risks to emergency access mechanisms are multi-faceted: Local proximity attackers can exploit short-range channels, demonstrating that physical presence is not a sufficient security boundary, especially when emergency protocols mandate permissive access (Halperin et al., 2008; Rasmussen et al., 2009). The more dominant threats relate to human factors and long-term deployments, including insider misuse and overreach, in which authorised personnel, under acute stress and cognitive load, inadvertently misconfigure devices, resulting in outcomes equivalent to a malicious act (Tandon et al., 2024; Sendelbach &

Funk, 2013; Bonney, 2011, p. 240; Sutton et al., 2020; Gündoğan & Erdağı Oral, 2023; Jämsä et al., 2021; Sarioğlu & Amarat, 2025). This vulnerability is compounded by accidental and stress-induced misuse, in which degradation in human performance under high-pressure conditions increases the likelihood of procedural errors (Tandon et al., 2024). Furthermore, the decades-long service life of IMDs introduces significant lifecycle and supply-chain degradation, making vulnerabilities due to outdated cryptography or poor key management a more dominant long-term concern than novel attack vectors (James et al., 2025). Consequently, effective policy and design must prioritise resilience against predictable human error, misaligned trust assumptions, and operational drift, rather than focusing predominantly on technical measures against less probable, high-sophistication remote cyberattacks.

6.1 Implications for Emergency Access Design

Under this revised threat model, the dominant risks to emergency access mechanisms arise from misplaced trust assumptions, stress-induced misuse, and lifecycle drift, not from adversaries with exceptional technical capabilities. Consequently, mechanisms that prioritise strong authentication or cryptographic complexity without addressing emergency usability and governance are unlikely to reduce net damages. These insights motivate the safety failure-mode analysis that follows.

7. Safety Failure Modes in Emergency Access

The IMD safety policy must integrate evidence from digital health, cyberphysical systems, and human-centred design, explicitly treating safety failures as co-equal determinants of patient harm along with security risks. Emergency IMD access is a safety-critical operation that occurs under significant stress, time pressure, and incomplete information. These are all conditions known to increase the likelihood of mistakes in people and systems, especially when they are not following their usual workflows (Tabassum et. al. 2018; Tandon et al., 2024). Security must not compromise robustness and usability in emergencies; an unusable, technically secure system is a direct safety hazard. Two dominant safety failure modes are access denial/latency and misconfiguration. Denials or delays in interventions can result from credential-, mediator-, or manufacturer-mediated access failing due to unavailable or slow credentials, intermediary devices, or external authorisations. Cyber-physical systems research shows that control-layer latency often causes outright failure, which is critical for IMDs, where seconds matter. These failures can occur even if security controls function, exposing a structural incompatibility between security assurances and emergency safety. Rapid parameter alteration in emergencies risks misconfiguration under stress. Research on human-centred systems suggests that unfamiliar interfaces or coarse-grained controls raise the likelihood of errors, a situation worsened by the variety of proprietary IMD interfaces (Beckers et al. 2016).

Usability failures and workflow disruption degrade safety. Complex authentication, precise timing, or unfamiliar tools are functionally equivalent to access denial. Digital health studies confirm that workflow disruption—not technical capability—dominates adverse outcomes in emergency digital interventions (Tandon et al., 2024). This evidence challenges the assumption of infrequent, flawless emergency use. Ethical risks regarding consent and autonomy arise when access overrides patient preferences. Poorly specified policies erode trust, a safety risk that systems research confirms affects acceptance and adherence (Beckers et al., 2016).

Summarily, these failure modes show that tighter security alone cannot ensure safe IMD emergency access. Any measure that blocks unauthorised use but adds delay or ambiguity increases patient harm. A shift from security-only fixes to systemic governance, accountability, lifecycle responsibility, and risk redistribution is essential to preserve institutional trust in these safety-critical systems.

Figure 1 and Table 1 illustrate the irreducible trade-off between access latency and security exposure. No mechanism can optimise both simultaneously; the curve represents a structural security-safety inversion. The central governance question is where to position mechanisms along this frontier in high-stakes contexts.

Table 1: Mapping mechanisms to their failure modes, dependencies and trust assumptions

MECHANISM	PATIENT SAFETY (Y-AXIS)	SYSTEM SECURITY (X-AXIS)	TRADE-OFF PROFILE	NOTES
Magnet-triggered override	Very High	Very Low	Top-left corner	Instant access; vulnerable to physical tampering or accidental activation
Proximity-based triggers	High	Low	Left of curve	Fast and intuitive; lacks authentication or audit trail
Break-glass protocols	Moderate	Moderate	Mid-curve	Requires clinician action; may log override, but still bypasses full authentication
Manufacturer-mediated access	Low	High	Bottom-right curve	Secure and auditable; slow and dependent on external coordination
Cryptographic authentication	Very Low	Very High	Far-right curve	Strongest security; impractical in emergencies without preloaded credentials
Pre-authorised clinician override	High	Moderate	Upper-mid curve	Balances speed and accountability; depends on trust in local personnel
Biometric triggers (experimental)	Moderate	High	Right of curve	Promising but unproven; latency and reliability concerns in crisis

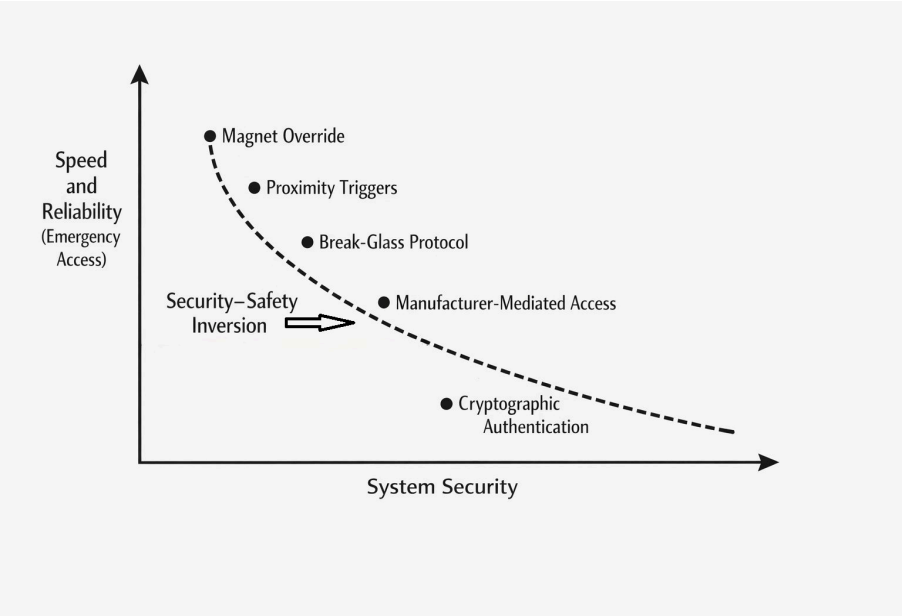

Figure 1: Pareto frontier diagram showing the irreducible structural tensions forcing trade-offs across essential dimensions of IMD operations

Together, Figure 1.0 and Table 1 show that these trade-offs are structural rather than incidental. They arise from the interaction of human performance under stress, IMD resource constraints, and governance expectations. As a result, emergency access design is not a search for optimal points but rather a process of selecting which risks are tolerable, for whom, and under what clinical and organisational conditions.

8. Governance, Accountability, and Risk Redistribution

Emergency access failures are governance gaps, not cryptographic deficiencies. Access denials arise when frameworks fail to mandate emergency access standards; misconfigurations reflect a lack of interface harmonisation and human-factor validation; lifecycle drift stems from weak manufacturer obligations; ambiguous authority reveals a failure to specify who acts under what conditions (Beckers et al., 2016). These are institutional, not technical, failures.

Emergency access is an exception regime that requires normative judgements about who acts, when, and with what consequences (Ison et al., 2025). Design choices encode governance decisions that policy must manage.

Authority allocation during emergencies directly affects safety. Clinician-centric models enable rapid action but impose liability; manufacturer-centric models offer traceability but introduce delays; hybrid models create ambiguity. Clear precedence rules are essential to prevent hesitation (James et al., 2025).

Each mechanism redistributes residual risk: proximity shifts risk to patients; break-glass transfers liability to clinicians; manufacturer mediation increases vendor complexity; context conditioning embeds risk in opaque algorithms. Explicit risk redistribution—not technical optimisation—is the core policy decision (Beckers et al., 2016).

Long device lifecycles and post-hoc logging complicate accountability. Regulatory silence on emergency cybersecurity exceptions incentivises conservative designs that minimise manufacturers' liability at the expense of patient safety (Maisel & Kohno, 2010; James et al., 2025).

Governance frameworks must recognise emergency access as a managed exception regime, aligning legal liability, clinical authority, and regulatory expectations in advance.

9. Comparative Synthesis and Irreducible Tensions

The design and governance of emergency access mechanisms for implantable medical devices (IMDs) prevent convergence on a single optimal technical solution. Instead, comparative synthesis reveals that these systems encode irreducible structural tensions, forcing trade-offs across essential dimensions such as access speed, resistance to malicious use, auditability, and clear governance. This dynamic is a recognised characteristic of tightly coupled safety-critical cyberphysical architectures: optimising one attribute inherently degrades performance in another. Therefore, analysing various emergency access strategies yields not a universally superior technical protocol, but rather a set of “bounded capability envelopes”, in which effectiveness is constrained by fundamental assumptions regarding trust models, urgency, and the assignment of operational responsibility. Any technical proposal that claims universal superiority likely fails to account for these fundamental, interlinked constraints.

A crucial policy insight is the security–safety inversion that occurs under emergency conditions. While controls prioritising security over safety are reasonable during a steady-state operation, their continuous enforcement can become counterproductive during a crisis. Emergency access is infrequent but invoked under extreme circumstances, and the denial or delay of access may pose a greater immediate risk to a patient than the threat of unauthorised use. Recent work in digital health emphasises the dominance of interventional and recovery capacities over pure prevention in crisis management (Tandon et al., 2024; Siddiqi et al., 2020). This inversion undermines conventional cybersecurity evaluation frameworks that emphasise access restriction without adequately accounting for time-critical safety constraints and the real-world operational demands of clinical emergencies.

Furthermore, efforts to manage IMD access inevitably lead to the redistribution of risk rather than its net reduction, with disagreements often rooted in contested views on acceptable risk allocation (Beckers et al., 2016). The core irreducible tensions that persist across all IMD emergency protocols—and those that resist purely technical or artificial intelligence solutions—include the conflict between immediate action and verifiable authorisation; the clash between simplified usability during a crisis and the detailed logging required for auditability; and the friction between centralised security control and necessary decentralised clinical autonomy. The design challenge is not the elimination of risk but the management of inherent tensions within a managed-exception space, where design choices explicitly trade off safety, security, and governance priorities. Future policy directions must focus on establishing explicit frameworks for allocating authority and responsibility, rather than seeking device-level technical optimisation.

10. Conclusion: Limits, Non-Solutions, and Future Directions

Synthesis of Findings

Emergency access to IMDs presents a structural tension: no single technical solution can simultaneously maximise security, safety, and accountability. Designs prioritising security risk fatal delays; those prioritising immediacy increase the potential for misuse. Enhanced technical controls—'perfect' authentication or universal backdoors—are non-solutions. The core constraints are institutional. Without explicit regulatory guidance on emergency exceptions, audit standards, and a clear allocation of responsibilities, proprietary mechanisms will continue to create ambiguity.

Prescriptive Governance Interventions

Addressing the structural tensions identified in this review requires governance interventions that reshape the constraint space rather than attempting to engineer around it. Regulators should establish minimum emergency-access performance standards, including maximum permissible access latency and requirements for predictable behaviour under degraded conditions. Manufacturers must be subject to lifecycle responsibility obligations, ensuring that emergency access remains viable, secure, and auditable throughout the device's multi-decade lifespan. Governance frameworks should mandate post-event auditability, requiring that all emergency overrides—whether successful or failed—are logged, reviewable, and linked to clear accountability structures. Cross-jurisdictional harmonisation is essential for avoiding fragmented expectations that undermine clinician autonomy and patient safety. Finally, procurement and certification processes should incorporate human-factors validation to ensure that emergency access mechanisms can be executed reliably under acute cognitive load and environmental stress.

Closing Statement

These interventions reposition governance as the primary mechanism for managing the unavoidable trade-offs between safety, security, and accountability. Technical innovation remains necessary, but without governance structures that explicitly define acceptable risk, emergency access will continue to fail in predictable and harmful ways.

Toward Better Use of Cyber Threat Models in Defence Environments

Steve.Johnson@soton.ac.uk
E.Karafili@soton.ac.uk

Abstract: Threat modelling in cybersecurity is a systematic process for identifying, analysing, and prioritising threats in a system. However, it is a highly challenging task in the defence sector, since military capabilities present a broad attack surface. This problem is compounded by the widespread use of civilian threat models, designed for specific systems or security aspects, in the defence sector, which often lack the breadth required to analyse military capabilities. In this paper, we identify gaps in state-of-the-art threat models in their ability to represent threats in the defence sector, using TEPIDOIL, a framework that captures the components required to maintain effective defence capabilities. We then present a novel framework called *Universal Defence Framework*, and demonstrate, through a case study and evaluation, that it enables the use of existing (civilian) threat models in the defence sector and addresses the identified gaps. Our evaluation showed that integrating threat models into our framework provides the broader view required to analyse threats in complex, integrated systems, as typically found in the defence sector.

Keywords: Threat modelling, Defence, TEPIDOIL, STRIDE, OCTAVE, Cyber kill chain

1. Introduction

In cybersecurity, threat modelling is a crucial process for identifying how adversaries can penetrate a system and escalate attacks. It identifies system components, how they can be compromised, and helps prioritise risks that pose the greatest harm to the system. Hence, threat models are highly useful for analysing system weaknesses.

Threat modelling is a key pillar in the planning and improvement of responses to attacks in the defence sector. However, there are three key problems. First, civilian threat models are typically designed for a specific system or security aspect, e.g., Cyber Physical Systems (Valenza et al., 2022), Internet of Things (Mahlous, 2023), software systems (Sion et al., 2021), human factors (Ferro et al., 2021), and others. Thus, unable to represent the complexity of the defence sector. Second, defence environments are often defined in terms of capabilities: the ability to perform an action or to deliver a service or function. Military capabilities rely on aspects that are not fully integrated in the civilian context, e.g., logistics, doctrine. Third, civilian threat models are used in defence environments, even though they typically do not provide the breadth required to analyse military capabilities with a broad attack surface. Hence, threat modelling in defence requires a broader perspective; otherwise, it would only partially represent a capability, creating blind spots.

In this paper, we address this problem by identifying the representation gaps threat models have when used in the defence context. In particular, we evaluate these threat models against TEPIDOIL, a UK Ministry of Defence (MoD) framework that captures the components required for maintaining effective defence capabilities (MoD, 2024). To address representation gaps, we introduce a novel *Universal Defence Framework* that enables the use of civilian threat models in the defence sector and captures critical defence components and capabilities.

To identify the gaps, we analysed three threat models used in both defence and civilian contexts. We evaluate these threat models by comparing their representation capabilities with respect to TEPIDOIL, which encompasses Training, Equipment, Personnel, Information, Doctrine and Concepts, Organisation, Infrastructure, and Logistics (MoD, 2024). Vulnerabilities in any of these components can impact the delivery of capabilities. For our analysis, we selected STRIDE (Kohnfelder and Garg, 1999), OCTAVE (Alberts et al., 2003), and Cyber Kill Chain (Hutchins et al., 2011), as they are popular approaches used for threat modelling (Suhas, 2023; Naik et al., 2024). While it is challenging to provide evidence of these threat models in critical defence scenarios (due to secrecy in this sector), they are frequently emphasised in defence documentation, as recommended or useful threat models.

Our analysis confirmed that these threat models cannot represent all TEPIDOIL components. To fill these gaps, we introduced our novel *Universal Defence Framework*, which enables the application of civilian threat models in the defence sector to facilitate comprehensive analyses of military capabilities. To showcase our framework, we present a case study on a military application. This case study clearly shows that it allows threat models to

represent defence aspects that could not be represented before. Our preliminary evaluation shows that our framework enhances the representation capabilities of threat models for the defence sector.

In Section 2, we present briefly the related works. In Section 3, we analyse each threat model to identify their representation gaps. In Section 4, we present our novel *Universal Defence Framework*. In Section 5, we present a case study demonstrating the application of our framework. In Section 6, we evaluate how our framework enhances existing threat models and discuss the limitations of our work. Finally, in Section 7, we conclude and provide future research directions.

2. Related Works

Threat models are crucial in identifying vulnerabilities in systems and software. Threat models are generally used for civilian contexts. Valenza et al. (2022) developed a threat model and tool that takes as input a system's digital, physical, and human assets and derives how threats can propagate through the system. Mahlous (2023) quantified the severity of harm caused by threats across different asset types in an Internet of Things system, using the STRIDE threat model. Sion et al. (2021) developed a tool that analyses threats in a software system during code updates, facilitating dynamic and automated threat modelling. Ferro et al. (2021) developed STRIDE-HF, a threat model that helps analysts identify how human-factor weaknesses (e.g., a lack of understanding) can enable cyberattacks. Sgandurra et al. (2016) presented a threat model for virtualized systems.

Let us describe three state-of-the-art threat models, i.e., STRIDE, OCTAVE, and the Cyber Kill Chain, that have been used in the defence sector, with examples of this usage.

STRIDE (Spoofing, Tampering, Repudiation, Information Disclosure, Denial of Service, Elevation of Privilege) (Kohnfelder and Garg, 1999) was originally designed for threat modelling software systems but has since been applied to other systems. STRIDE, combined with Data Flow Diagrams (DFDs), is particularly useful for classifying threats into each of the six categories by asking, for example, 'Is there a possibility for an adversary to present as another entity to exploit this part of the system, and what threats can allow this?' (e.g., Spoofing threats). A notable implementation of STRIDE in defence is the guidance proposed by the UK Department for Science, Innovation & Technology (DSIT, 2024) for threat modelling smart-city-related technologies using STRIDE. The guidance presents four cases in which local authorities have deployed the approach to identify threats across different contexts, including IoT devices, connected safety devices, and air quality sensors.

OCTAVE (Operationally Critical Threat, Asset, and Vulnerability Evaluation) (Alberts et al., 2003) is a threat model that has three key phases. The first phase requires threat modellers to identify organisational assets in order to identify critical assets that, if compromised, have a significant impact on the business. The second phase involves identifying and analysing the components that enable crucial assets to function as expected, as well as weaknesses. Finally, the third phase requires analysts to develop countermeasures to address the identified vulnerabilities. While information on the application of OCTAVE in defence is often classified, research sponsored by the US Department of Defence (Woody, 2006) indicates that training is provided to medical teams to conduct risk assessments of healthcare systems using OCTAVE, identify and prioritise security risks, and formulate countermeasures.

Cyber Kill Chain (CKC) (Hutchins et al., 2011) is designed to decompose cyberattacks into seven phases that detail how adversaries collect the information required to conduct the attack, how an exploit is built, and how exploits are delivered. The threat model is useful for a range of scenarios. First, before a cyberattack, the CKC can be used by organisations to plan how they will manage each stage. Second, when managing a live attack, the CKC can be used to predict adversarial actions. Third, the CKC can be used to analyse why and how a cyber-attack occurred by reconstructing a series of events. A notable implementation of the CKC in defence is by the US Marine Corps, which deployed a red/blue teaming activity to test how well attacks against critical infrastructures could be defended against realistic attack scenarios (Corbo, 2022). The CKC was used to design multiple attack scenarios, in stages that mirror the progression of real attacks.

3. Analysis of Threat Models

In this section, we introduce TEPIDOIL and analyse STRIDE, OCTAVE, and CKC with respect to their ability to represent TEPIDOIL elements. Our analysis finds that these models cannot fully represent and analyse TEPIDOIL elements, as shown in Table 1.

TEPIDOIL is a framework that defines components that facilitate an effective military capability. A capability refers to the ability of a defence organisation to perform an action or to deliver a service or function (MoD,

2024). Each component of TEPIDOIL can introduce threats; hence, for a capability to be effective, all components must avoid significant compromise. This highlights that capability-based threat modelling must consider a broad range of systems and components. TEPIDOIL's components can be defined as ensuring the following: (1) Training: Ensuring that individuals are proficient in conducting their responsibilities well; (2) Equipment: Ensuring the availability and effectiveness of software or physical tools that support the capability; (3) Personnel: Ensuring individuals with the correct expertise and ethical conduct can support the desired outcomes; (4) Information: Ensuring that data is only accessible by authorized parties, that it remains available and untampered by unauthorized parties, and is processed securely; (5) Doctrine and Concepts: Ensuring that military forces are guided by robust processes, frameworks, and guidelines; (6) Organisation: Ensuring that there are structures in place to facilitate defence objectives, particularly regarding management structures, and how roles interact with each other; (7) Infrastructure: Ensuring that there are structures required to aid defence objectives (e.g., buildings); (8) Logistics: Ensuring that approaches are sustainable (e.g., developing maintainable assets and tools).

Our analysis on *STRIDE* identified gaps or partial representation in seven of eight TEPIDOIL elements. In particular, (1) Training: STRIDE can model the platform used for training (e.g., Denial of Service threat: training platform can be disrupted), but key threats, such as how an individual's skill can degrade during the lifecycle of capabilities, cannot easily be derived; (2) Equipment: Software equipment can effectively be analysed in STRIDE, though, since it is information-centric, physical threats are less derivable from DFDs or analyses; (3) Personnel: STRIDE is limited in being able to derive the reasoning behind human factor errors (e.g., fatigue); (4) Information: The model is comprehensive in identifying information security threats; (5) Doctrine and Concepts: STRIDE can represent doctrine and concepts (e.g., guidelines) as assets, however, the suitability of doctrine for capabilities is not assessed; (6) Organisation: While STRIDE allows practitioners to identify information flow through the system, threats that arise from governance, for example, in a team, are not analysed by default; (7) Infrastructure: In STRIDE, components of the system are organised into boundaries (e.g., with DFDs), however, STRIDE does not often consider this from a physical point of view, though some physical implications can be analysed using denial of service or tampering categories; (8) Logistics: Threats impacting how well a capability can be sustained are challenging to derive without additional prompts.

Our analysis on *OCTAVE* found that it overall covered more elements, with two TEPIDOIL elements covered and the rest partially covered. In particular, (1) Training: The first phase in OCTAVE can identify weaknesses in the organisation, which can include those related to training, however, the documentation (Alberts et al., 2023) emphasises the assets themselves; (2) Equipment: OCTAVE identifies critical assets well, but gives less attention to specific software or physical equipment vulnerabilities than other models, e.g., STRIDE; (3) Personnel: Human-factor risks may emerge in Phase 1, but they are not strongly emphasised and can be overlooked. (4) Information: Information threats are well covered, as Phase 1 includes identifying key data assets. (5) Doctrine and Concepts: OCTAVE assesses policy and guideline compliance rather than weaknesses in doctrine itself; (6) Organisation: Risks from organisational roles and governance can be identified; (7) Infrastructure: Phase 2 analyses infrastructure supporting business functions, but mainly when tied to a crucial asset rather than as a risk source on its own; (8) Logistics: Logistics related threats (e.g., delivery capacity or timing) are not addressed by default unless analysts explicitly apply TEPIDOIL.

Our analysis on *CKC* found that it can represent three TEPIDOIL elements, partially represent two, and cannot represent three. In particular, (1) Training: CKC can place training weaknesses within an attack sequence, but it does not evaluate training threats directly, and training is rarely the primary target; (2) Equipment: Equipment attack paths can be mapped clearly through the step-by-step phases of the model; (3) Personnel: Human-factor weaknesses (e.g., exploited through phishing) can be represented, but CKC is not designed to analyse them in depth and often treats them only as attack initiators; (4) Information: The model can specify how information assets can be impacted (e.g., with the actions on objectives stage); (5) Doctrine and Concepts: Doctrine may be treated as an asset that can be attacked, but threats arising from doctrine itself receive little emphasis; (6) Organisation: Reconnaissance may capture organisational details, but CKC is less effective for deriving organisational risks than models like OCTAVE; (7) Infrastructure: The model effectively maps attacks on networks and physical architectures, including pathways to compromise; (8) CKC can illustrate disruption of logistical processes, but detailed analysis may require adaptation or explicit prompting.

Our analysis has highlighted gaps in the representation of TEPIDOIL elements in these threat models (see Table 1). Although each model can comprehensively represent the information component in TEPIDOIL (i.e., derive information-security-centric threats), analysts would require explicit prompting to consider other components

(e.g., training or logistics). Without this, analysts may produce threat models that only partially represent the threats in a capability because a standardised process has not been used.

Table 1: Gaps summary. ✕ = not typically captured; ◑ = requires explicit consideration; ✓ = well captured by default

Element	STRIDE	OCTAVE	CKC
Training	◑	◑	✕
Equipment	◑	◑	✓
Personnel	✕	◑	◑
Information	✓	✓	✓
Doctrine and Concepts	◑	◑	✕
Organisation	✕	✓	✕
Infrastructure	◑	◑	✓
Logistics	✕	◑	◑

4. Proposed Approach: Universal Defence Framework

In this section, we introduce our *Universal Defence Framework*, designed to enable analysts to comprehensively analyse military capabilities using a threat model of their choice to identify threats. Our framework is a general extension that enhances existing models. This addresses a key limitation of civilian threat models highlighted in Section 2: they are not optimal for analysing capabilities by default. Note that our proposed approach is a general framework that enhances most threat models, rather than addressing specific limitations in STRIDE, OCTAVE, or CKC, which provide different functionalities.

Our framework has four main concepts: *capabilities*, *functions*, *assets*, and *failure modes*. A capability is the ability to perform an action or deliver a service or function (broad view). Functions are the aspects that enable a capability to be effective (more descriptive). Assets are the people, processes, and technologies required for functions to operate (granular details). Finally, failure modes denote states of assets or functions (e.g., compromised, degraded, or normal).

Our framework, presented in Figure 1, consists of four key stages, each with associated processes. In Phase 1, analysts contextualise further analysis to the capability by (i) defining the capability, (ii) defining the functions that enable the capability, (iii) defining failure modes in the functions, and (iv) defining unacceptable compromises to the capability. In Phase 2, analysts identify the assets involved in making the functions work by (i) identifying TEPIDOIL assets (people, processes, and technologies) required for each function from Phase 1, and (ii) defining failure modes for every asset. In Phase 3, analysts identify threats to assets by (i) selecting the threat model(s), e.g., STRIDE, OCTAVE, CKC, etc., (ii) applying the threat models(s) to each asset from Phase 2 to identify threats, and (iii) evaluating how each threat against an asset would cause a failure mode in the asset and the functions that depend on the asset. Finally, in Phase 4, analysts (i) evaluate the impacts of failure modes triggered in functions (from Phase 3) on the capability, considering the conditions from Phase 1, Process (iv).

Figure 1: Universal Defence Framework

5. Case Study

In this section, we demonstrate the application of our framework through a case study, which is a conceptual example of a capability presented in an MoD advisory.

Let us introduce the case study (MoD, 2025). During missions, military forces are delivered supplies (e.g., power and medical aid) via Unmanned Aerial Vehicles (UAVs). To enable personnel to collect their supplies, they must be able to track the UAV and receive relevant delivery information via military software on their mobile phones. A capability refers to the ability to perform an action or to deliver a service or function. Hence, in our case study, capability refers to the ability to track the UAV effectively using software, and threats to TEPIDOIL elements can affect the execution of this capability.

We now demonstrate how our framework can be applied to this capability, showing how the processes in our proposed framework align with threat models such as STRIDE.

Phase 1: Contextualise to the capability.

- *Process 1: Define the capability:* Software must allow military personnel to track the UAV in conflict environments reliably.
- *Process 2: Define functions that enable the capability:* (1) Authenticate users [F1], (2) Allow delivery tracking [F2].
- *Process 3: Define failure modes in the function:* For simplicity, all functions will have the following failure modes: Normal (N), Degraded (D), Compromised (C).
- *Process 4: Define unacceptable compromises to the capability:* (1) Death of military personnel [UC1], (2) Delivery information about supplies is disclosed [UC2].

Phase 2: Identify assets.

- Process 1: Identify TEPIDOIL assets (people, processes, technologies) required for functions to work:

Simplified example (in-depth analysis can include more assets):

- For F1:
- *People: Military personnel (Personnel)*
- *Processes: Access token must be issued (Equipment)*
- *Technologies: Mobile phone (Equipment); software (Equipment)*
- For F2:
- *People: Military personnel (Personnel)*
- *Processes: Updates to delivery progress (Equipment)*
- *Technologies: UAV telemetry (Equipment); software (Equipment)*
- *Process 2: Identify failure modes for assets:* For simplicity, modes for all assets are *normal (N)*, *degraded (D)*, or *compromised (C)*, but these can be specified further.

Phase 3: Identify threats.

- Process 1: Select the threat model(s): STRIDE
- *Processes 2 and 3: apply threat model to each asset (from Phase 2) to identify threats, and for each threat evaluate how it can cause (→) a failure mode in the asset and a failure mode in the functions that depend on the asset.*
- Military personnel:
- *Spoofing: Adversaries obtain user credentials via a successful phishing email and enter the software using those details. [Military personnel: C → F1:C, F2:C].*
- *Information disclosure: Military personnel reveal UAV delivery information to unauthorised parties. [Military personnel: C → F2:C].*
- Access tokens:
- *Spoofing: Adversaries impersonate military personnel by replacing tokens. [Access token: C → F1:C, F2:C]*
- *Tampering: Adversaries modify tokens. [Access token: C → F1:C, F2:C]*
- *Information disclosure: Adversaries extract tokens from data stores. [Access token: C → F1:C, F2:C]*

- Mobile phone:
- *Spoofing: Adversaries steal the mobile phone to imitate military personnel. [Mobile phone: C → F1:C, F2:C]*
- *Denial of service: Damage to the device prevents personnel from using tracking software. [Mobile phone: D → F1:D, F2:D]*
- Software (UAV tracking software):
- *Tampering: Adversaries modify software code. [Software: C → F1:C, F2:C]*
- *Information disclosure: Adversaries access software artefacts stored on a programmer's device. [Software: C → F1:C, F2:C]*
- *Denial of service: The app malfunctions. [Software: C → F1:C, F2:C]*
- *Elevation of privilege: Poor authentication processes result in personnel accessing delivery information outside of their role. [Software: C → F1:C, F2:C]*
- UAV telemetry:
- *Spoofing: Adversaries fabricate telemetry [UAV telemetry: C → F2:C]*
- *Denial of service: Adversaries jam telemetry, preventing UAV tracking. [UAV telemetry: C → F2:C]*
- Updates to delivery progress:
- *Tampering: Adversaries modify delivery updates. [Updates to delivery progress: C → F2:C]*
- *Repudiation: There is no auditing for personnel who updated the delivery progress. [Updates to delivery progress: C → F2:C]*
- *Denial of service: There are delayed updates, hindering prompt updates [Updates to delivery progress: D → F2:D]*

Phase 4: Analyse impacts on the capability.

- For each function compromised, analyse impacts on the capability, considering unacceptable conditions specified in Phase 1, Process (iv).
- *All threats that compromise the crucial assets have resulted in compromised/degraded functions, e.g., C → F1:C, C → F2:C, C → F1:D, or C → F2:D.*
- *For simplicity, threats are abstracted, but every threat identified can be analysed for the impact on the capability, e.g.,*
- F1 compromised [F1:C], e.g., can result in threat actors masquerading as genuine users, resulting in UC2 (compromised capability).
- F1 degraded [F1:D], e.g., can result in personnel not being able to authenticate, resulting in UC1 (compromised capability).
- F2 compromised [F2:C], e.g., can result in delivery information being disclosed, resulting in UC1/UC2 (compromised capability).
- F2 degraded [F2:D] e.g., can result in UC1 or UC2 (compromised capability).

Our case study shows how our proposed framework can be applied to comprehensively analyse defence capabilities: in Phase 1, we defined the capability (e.g., the ability to track the UAV), functions that enable the capability (e.g., software should allow tracking), and unacceptable compromises (e.g., death of military personnel); in Phase 2, we identified TEPIDOIL assets required for functions to be executed (e.g., UAV telemetry); in Phase 3, we used STRIDE to identify threats to assets (e.g., adversary jamming of UAV telemetry) and the impact on functions (e.g., military personnel can no longer view accurate delivery information); and in Phase 4, we analysed how compromised functions can lead to unacceptable consequences (e.g., the death of military personnel) that compromise the broader capability.

6. Evaluation and Discussion

Let us discuss the additional features that our proposed framework provides compared with using threat models alone (see Table 2 for a summary). To begin, STRIDE, OCTAVE, and CKC are not contextualised with respect to what a capability aims to achieve. Hence, they primarily elicit threats and deconstruct attacks, without a strong link to capabilities. Our framework enables all analyses to be linked to the functions a capability aims to achieve. In addition, STRIDE, OCTAVE, and CKC provide limited guidance on what must be maintained for capabilities to be effective (though OCTAVE does so in part with respect to organisational security objectives). In our framework, we explicitly prompt analysts to define unacceptable compromises, thereby enabling analysis of the impacts of threats on the broader capability. Furthermore, STRIDE, OCTAVE, and CKC do not explicitly focus on analysing TEPIDOIL components, which is required for a comprehensive analysis of military capabilities. This can

result in analysts missing crucial threats and thus creating threat models that can only partially represent a capability (creating blind spots). In our framework, we explicitly prompt analysts to identify the TEPIDOIL assets (people, processes, and technologies) that enable a capability before threat analysis. Moreover, STRIDE, OCTAVE, and CKC do not explicitly prompt analysts to delineate failure modes in assets and functions that enable capabilities. Our framework is designed to prompt analysts to specify failure modes for both assets and functions, and to explain how a failure in an asset can cause a failure in a function, thereby compromising a capability.

Table 2: Comparison of features. ✕ = not addressed; ◑ = partially addressed; ✓ = addressed

Aspect	STRIDE	OCTAVE	CKC	STRIDE/OCTAVE/CKC + Universal Defence Framework
Explicit definitions of the capability underpin threat analysis.	✕	◑	✕	✓
Analyses the impact of threats on the capability based on defined unacceptable compromises.	✕	◑	✕	✓
Explicit focus on analysing TEPIDOIL components (often found in capabilities).	✕	✕	✕	✓
Explicit definitions of failure modes for assets and functions.	✕	◑	✕	✓

Integrating TEPIDOIL components into our framework can broaden the perspective applied to threat modelling. That broader view is often crucial when analysing threats in complex, integrated systems, as found in the defence sector. Table 3 shows that our proposed framework serves as a standardised extension that integrates threat models to comprehensively analyse capabilities.

Table 3: Summary. ✕ = not typically captured; ◑ = requires explicit consideration; ✓ = captured by default

Model	STRIDE/OCTAVE/CKC + Universal Defence Framework
Training	✓
Equipment	✓
Personnel	✓
Information	✓
Doctrine and Concepts	✓
Organisation	✓
Infrastructure	✓
Logistics	✓

Our work has two main limitations. First, we did not address the specific TEPIDOIL limitations of STRIDE, OCTAVE, and CKC identified in Section 2 by extending any specific model. However, our framework has a broad scope for the types of threat models that can be integrated, as it is generally applicable. Second, our work presents a case study using STRIDE but does not address how to resolve conflicts between processes already provided in threat models (e.g., OCTAVE) and those in our framework.

7. Conclusion and Future Work

In this paper, we address a key problem in threat modelling in defence environments. In particular, civilian threat models are widely used in defence; however, they typically do not provide the breadth required to analyse military capabilities that have a broad attack surface. In our paper, we evaluated state-of-the-art threat models used in both defence and civilian contexts to identify gaps in their ability to capture defence aspects. Our comparative analysis, using the TEPIDOIL framework for defence capabilities, found that threat models were unable to capture TEPIDOIL aspects. To address this problem, we introduced the *Universal Defence Framework*, a novel approach that enables existing threat models to conduct comprehensive, rigorous analyses of

capabilities. We presented a case study to demonstrate how our framework can be applied and have evaluated it against the use of threat models alone. Furthermore, our evaluation highlighted that explicit prompting within our framework to define TEPIDOIL assets (people, processes, and technologies) provides the broader view required when analysing threats in complex, integrated systems, as typically found in the defence sector.

An interesting research direction is to develop a prioritisation scheme to help select threats that cause the greatest harm to the capability. This prioritisation scheme can specify how to prioritise assets prior to the threat analysis. To broaden the scope of application, we plan to deploy the proposed approach in a more in-depth case study, including the use of OCTAVE and CKC. Another interesting future work is to collect feedback from defence stakeholders on the usability of our framework. Furthermore, we plan to develop guidance on resolving conflicts arising from integrating multiple threat models into our *Universal Defence Framework*.

Abstract: An Early Warning System (EWS) is a framework or collection of tools developed to identify and deliver timely alerts about potential threats, risks, or adverse events across various situations. Its main objective is to support decision-makers in implementing preventive actions that reduce the impact of possible hazards or disasters, thereby protecting lives and resources. Modern digital society depends on the interconnection and collaboration of essential infrastructures, which require adequate situational awareness (SA) to manage growing cyber risks. In the cyber domain, a key priority is safeguarding critical infrastructure (CI) against threats amid a surge in both the frequency and sophistication of cyberattacks. These evolving attacks allow adversaries to disrupt vital services remotely, creating significant risks and uncertainty in the absence of adequate SA and thus protection. The Cyber Early Warning System (CEWS) is essential within the cyber domain, integrating for example artificial intelligence (AI) to introduce a new approach to early warning capabilities. As a component of the cyber threat intelligence (CTI) process, CEWS offers an innovative methodological framework for navigating and operating in today's complex cyber environment. In large networked systems, CEWS gathers and correlates heterogeneous information from multiple sources, delivering timely and actionable insights to help prevent or mitigate potential risks by supporting effectively an organization's SA. Security Operations Center (SOC) is a key element to protect an organization's digital assets by continuously monitoring, detecting, investigating, and responding to cyber threats. The SOC is an essential part of an organization's SA and risk management, as it particularly supports risk identification, monitoring, and control by continuously providing information to detect, assess, and manage cybersecurity risks. This paper highlights the importance of collaborating with the Cyber Early Warning System and the Security Operations Center.

Keywords: Organization, Cyber early warning, Security operations center, Risks assessment

1. Introduction

Modern society depends on the coordinated, reliable performance of many critical infrastructure (CI) organizations, whose collective success increasingly relies on a resilient national system-of-systems. Because today's digital environment is tightly interconnected, organizations must maintain real-time situational awareness (SA) of cyber threats to manage growing risks to their assets. As cyberattacks become more frequent and sophisticated, protecting essential organizations has become a top priority. These evolving threats allow adversaries to remotely disrupt vital services, heightening risks and uncertainty, especially when organizations lack sufficient SA and the safeguards needed to support effective risk assessment.

Throughout history, societies have developed early warning systems to detect and respond to threats. Prior to modern technology, cities relied on external outposts to identify and signal approaching dangers. Today, states employ advanced surveillance systems, including radar and satellite technologies, to continuously monitor their borders and environments. These systems enable timely detection of emerging threats and facilitate appropriate defensive responses. An Early Warning System (EWS) refers to a set of tools or mechanisms designed to identify potential risks and provide timely information, supporting decision-makers in implementing preventive measures to mitigate impacts and protect lives and resources (Ultimaco, 2025).

Today a Cyber Early Warning System (CEWS) is needed in the context of the cyber domain. It incorporates artificial intelligence elements to enable a new approach to early warning capability. CEWS is part of the cyber threat intelligence process and provides a new methodological framework for operating in a complex cyber environment.

According to the EU NIS2 Directive, "essential and important entities should take appropriate and proportionate technical, operational and organizational measures to manage the risks posed to the security of network and information systems which those entities use for their operations or for the provision of their services, and to prevent or minimize the impact of incidents on recipients of their services and on other services" (EU, 2023). Identifying cyberattacks are increasingly difficult, and the fast-changing nature of cyber environment demands both agility and preparedness for unforeseen threats. While risk assessment methods can address most known and partially known events, completely unknown threats require alternative approaches.

The definition of the research problem emphasizes the challenges of proactively identifying unknown risks that threaten an organization's cybersecurity and leveraging that information within operational processes. In this sense, CEWS is needed to develop an extended approach for providing better CTI to support an organization's operational purposes in a complex cyber environment. It is an important threat-intelligence process, particularly for identifying unknown threats and enhancing situational awareness in organizational risk-assessment activities. In many cases, these unknown threats are associated with dark-web entities.

Threats are characterized by the motivation and capabilities of threat actors. For example, such attributes are not directly observable within traditional risk assessment processes, particularly in environments such as the dark web. This information can, however, be inferred from multiple sources using CEWS and by leveraging advanced technologies, such as Artificial Intelligence (AI). The aim of this study is to evaluate the applicability of such information across different stages of the Security Operations Center (SOC) process, and thereby as part of an organization's overall risk assessment.

SOC forms the operational core of an organization's cyber defense capability. It is mainly reactive element, because its purpose is to detect, investigate, and respond to security incidents A SOC is more than just a 'technical monitoring center'; it is an integral part of an organization's real-time situation awareness tool and part of overall risk management strategy. It plays a key role in two main areas: identifying and monitoring risks and managing and responding to them effectively. In this role, the SOC relies on relevant CI to guide its actions. An effective CEWS is a key element in building that awareness and, consequently, an integral part of the organization's overall robust risk management process. This paper outlines the structural domains of SOC, from strategic steering to proactive prevention, describing how each contributes to the overall life cycle of threat management and operational assurance. The model presented here is designed to be framework-agnostic, scalable, and suitable as a foundation for further research and capability development.

In this paper, we examine the importance of a Cyber Early Warning System (CEWS) as part of Security Operations Center (SOC) operations. The paper emphasizes the importance of CEWS data for the SOC process at different stages in order to manage unknown risks proactively. Technically, CEWS data can be integrated with the SOC's Security Information and Event Management (SIEM) system. The research framework outlines the structure of risk categorization, while the empirical part focuses on the SOC process. The main question is:

'What are the key elements for the cooperation between CEWS and SOC in risks identification?"

2. Cyber Security Situational Awareness

Cybersecurity situational awareness is the real-time understanding of the digital environment, including emerging threats, vulnerabilities, and the potential impact of attacks, to enable timely and effective responses. It involves perceiving events, comprehending their significance, and projecting potential future scenarios. Achieving this requires robust data collection, advanced analytics, and effective information sharing.

There are three key components to creating a situational picture: (Endsley, 1995)

- Perception of the elements in the environment
- *The goal is to perceive the status, attributes, and dynamics of relevant elements in the environment.*
- Comprehension of the situation
- *This involves a synthesis of elements through the processes of pattern recognition, interpretation, and evaluation.*
- Projection of future status
- *This involves the ability to project the future actions of the elements in the environment.*

In his article "Flow Analytics for Cyber Situational Awareness", Sid Faber considers measures to develop situational awareness in both public and private organizations to be among the most significant near-term objectives for improving cybersecurity. Faber recommends applying the framework developed by Endsley to the monitoring requirements of the cyber operational environment. (Faber, 2015)

3. Risk Categorization as a Research Framework

Effective risk assessment requires systematically collecting and analyzing data while accounting for evolving threats and vulnerabilities. It helps raise awareness, prioritize early warning systems, and guide disaster prevention and response.

Risk knowledge depends on an up-to-date understanding of the cyber environment, including current events and changing threat actors. Since these changes happen quickly, maintaining continuous situational awareness is essential.

Threats can be categorized as immediate (e.g., ongoing cyberattacks on critical infrastructure) or long-term (e.g., geopolitical risks). Managing cyber risk relies on accurate awareness of risks and impacts. While more information improves risk management, unknown risks ("unknown unknowns") remain difficult to predict and are often outside traditional risk planning.

Figure 1 shows a schematic structure of risk categorization. In this table, the model categorizes events by "identification" and "accuracy of knowledge or certainty". (Kim, 2012, mod)

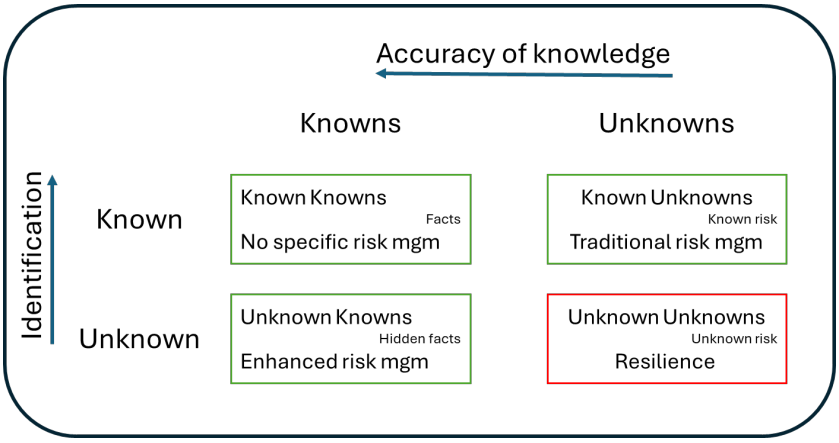

Figure 1: Schematic structure of modified risk categorization

The first three categories of events (known knowns, known unknowns, and unknown knowns) can be addressed through established risk assessment methods and processes. However, completely unknown possibilities require a different approach. To address these, organizations must enhance the overall resilience of their business operations, for example by implementing a Cyber Early Warning System (CEWS) integrated with Security Operations Center (SOC) activities.

4. Early Warning System

Early warning systems (EWS) are essential for example climate action because they provide timely alerts about hazards such as floods, droughts, and wildfires, helping save lives and reduce damage. Despite global progress, challenges like limited funding, data gaps, and communication issues remain, requiring continued cooperation. For long-term effectiveness, these systems must be continuously maintained and improved. The Third International Conference on Early Warning (2006) produced a practical checklist under the Hyogo Framework for action, outlining four key components of effective, people-centered early warning systems to help governments and communities strengthen disaster risk reduction (Figure 2). (ISDR, 2006)

EWS is a key tool that alert communities to hazards, giving time to prepare. They must be adaptable, regularly updated, and upgraded. Using tech like machine learning, data analytics, and advanced environmental monitoring improves warning accuracy and speed. Ongoing maintenance and enhancements are essential for EWS to remain effective and sustainable. (Sakalouskaya, 2024)

Figure 2: Four key elements of an early warning system

An effective EWS requires timely, clear, and unambiguous communication of information, while accounting for recipients' capacity to interpret and act on alerts. Warnings must be accurate and actionable, with thresholds calibrated to avoid both alert fatigue and insufficient notification. Additionally, information should be tailored to different decision-making levels.

For early warnings to support system defense, recipients must have predefined procedures, methods, and automation in place to process alerts efficiently. They must also understand EWS's operational logic, terminology, and resources, and be able to critically apply its outputs to protect the system.

In cyberdomain, Cyber Early Warning System's (CEWS) main focus is to give key information to decision makers and security teams about emerging threats before they happen. By having that information and using it appropriately in the decision-making process, it is possible to prevent the oncoming attacks at the early stage. EWS in cyber domain is a system or prosess of collecting and analyzing data from all layers of internet, surface web, deep web and dark web. By collecting and analysing the data it is possible to gather cyber threat information (CTI) of emerging cyber threats. By getting information about emerging cyber threats, it is possible to start preventive measures to defend against attacks before they reach the protected system or even occur in first place. CEWS is situated to work before attack triggers traditional indicators like Indicator of Compromise (IoC). Those early signals can be for example data found from data leaks, new tactics, techniques, and procedures (TTP's) of threat actors, new vulnerability in the system, device or protocol in use, discussions about protected organization in various darkforums, geopolitical events, and for example attacks occurring in the same region, operating sector, organizations supply chain, or for example against same field of political thinking.

Regarding the future development of CEWS, the primary focus will be on identifying an appropriate baseline model for performance evaluation and on developing an automated method to determine the date when a cyber threat becomes publicly known. Additionally, the method will undergo continuous refinement to enable the generation of more detailed and informative alerts. Future iterations will also incorporate a Natural Language Processing (NLP) component aimed at extracting relevant knowledge and insights from network posts that reference the identified terms. (Sapienza & al., 2017)

By implementing automating technologies and methods such as Large Language Models (LLMs), Machine Learning (ML) and Natural Language Processing (NLP) to CEWS, it is possible to utilize the enormous amount of information that internet provides in a rapidly changing environment. It is not possible to go through this information manually and find key information about early warning signals from multiple large scaling sources. In Figure 2 we show the flowchart from the initial sources of information to the cyber early warning signal and until receiving and reacting to that information.

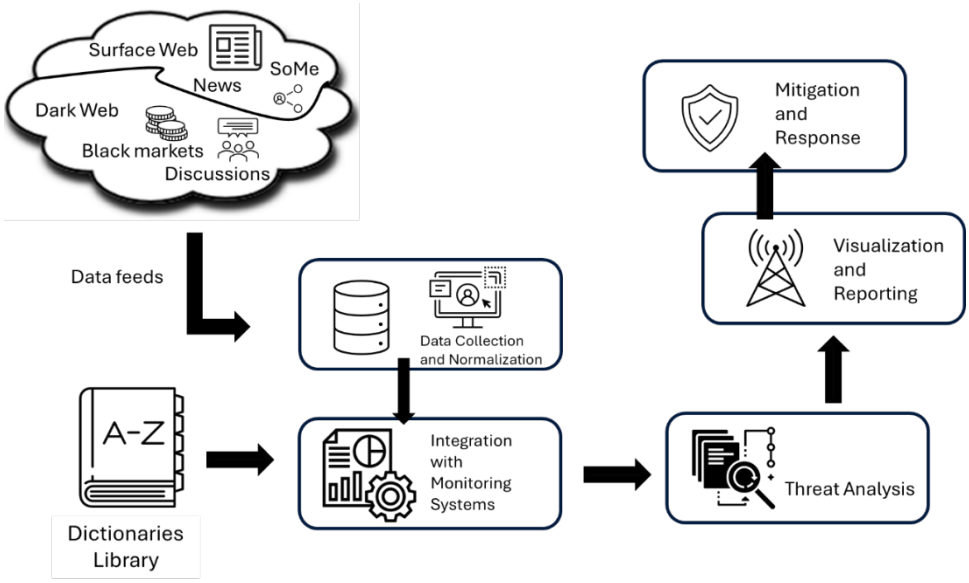

Figure 3: Cyber Early Warning System (CEWS)

Process starts with the dataset. There are enormous amounts of data that can be collected from different layers of internet. Data consists of, for example Surface Web's different news pages and social media sites or Dark Web's different black markets and discussion forums. The data is then collected and normalized and added to monitoring system. According to the needs of the operating environment, various dictionary-like filters are defined, which are used to collect essential information from the data for analysis. The material that passes through the filters is analysed and various risk assessments are made based on the analysis. This information is compiled into an easy-to-understand report. Based on that report defensive measures can be adjusted, and risks can be mitigated.

5. Cyber-physical Environment

The cyber-physical environment combines physical reality and digital technologies through various networking methods. The most extensive and comprehensive solution is the internet. With internet networking solutions it is possible to connect physical processing tools to systems anywhere in the world with internet connectivity.

The Internet consists of three different layers: the surface web, the deep web, and the dark web. Each of these has its own role and characteristics with the content and purpose of the network (Lehto & Koskimäki, 2025). This knowledge of the different levels of the network is important, since the Cyber Early Warning System (CEWS) model, collects data from these different levels of the network.

Surface Web

The surface web, i.e. the visible web, is the top layer of the internet that can be accessed using regular web browsers (Khera, 2020). The surface web is the part of the internet that is openly available and easily accessible to all internet users. It is indexed by search engines and easily searchable through various search engines. Using surface web with default settings and browsers, without for example VPNs, leave trace from user, for example users IP-address and cookies collected by websites and internet services. (Varma, 2018)

Deep Web

Although the deep web may seem obscure, people use it constantly. Activities like email, private messaging, online banking, and accessing subscriber-only news all rely on it. (Vienažindytė, 2021) The deep web consists of online content that search engines cannot index, such as internal organizational databases, paywalled material, dynamically generated pages, and content accessible only through a site's own search tools. (Hatta, 2020) Estimates over the years have shown that the deep web is vastly larger than the surface web, making up most of all online information. Because the internet contains an enormous and ever-changing volume of data, the exact proportion between the surface web and deep web cannot be precisely measured, but most online content belongs to the deep web. (Finklea, 2017)

Dark Web

The dark web is a hidden section of the internet that cannot be accessed with standard surface web browsers. It enables users to remain almost entirely anonymous by encrypting data and sending it through multiple network nodes. In practice, a dark web user's traffic is routed through the network terminals of many other users, making it extremely difficult or impossible to identify the original source of the network traffic. This layered routing system is known as the "onion network," reflecting its multiple levels of encryption. The strong anonymity it offers draws people who want to keep their activities concealed. In the first hand, dark web was used by journalists and freedom activists of the authoritarian states. The dark web is nowadays known for its illegal marketplaces, the distribution of harmful or forbidden content, cybercriminal and espionage networks among other illicit activities. (Chertoff & Simon, 2015)

6. Security Operations Center

This chapter describes the core structural domains of a Security Operations Center (SOC), ranging from strategic oversight to proactive threat prevention, and explains how each domain supports the full lifecycle of threat management and operational assurance. The proposed process model is framework-agnostic, scalable, and intended to serve as a foundation for future research and capability development. A SOC forms the operational core of an organization's cyber defense capability. Its purpose is to detect, investigate, and respond to security incidents while continuously improving the organization's situational awareness and resilience. SOC functionality includes both process and technical components. According to our research, the appropriate structural process elements are as follows:

Steering

Steering function defines the mechanisms through which a Security Operations Center (SOC) aligns its activities with an organization's overarching risk management objectives. Effective steering is characterized by a deliberate balance between situational awareness and operational performance. Fundamentally, steering governs the allocation and coordination of the three core resources underpinning any security capability: people, processes, and tools. Through this governance, steering enables the transformation of the SOC from a primarily reactive technical function into a structured, managed capability that contributes directly to the organization's resilience and its strategic risk posture.

Visibility

Visibility constitutes the foundational element of all Security Operations Center (SOC) activities. It reflects the SOC's capacity to observe, understand, collect and store event information occurring within an organization's digital environment. This capability is fundamentally data-driven, relying on the continuous and voluminous streams of telemetry generated by organizational assets, systems, and services during normal operation. SOC visibility is derived from three primary sources. First, transactional data, which is obtained from telemetry and event logs, provides detailed records of system and user activity. Second, threat intelligence supplies awareness of external threats and adversarial behaviours relevant to the organization. Third, contextual information describes the organization's assets, configurations, and established patterns of normal behaviour, enabling meaningful interpretation of observed events. Collectively, these sources of visibility support both detection and decision-making within the SOC. Visibility functions as the analytical lens through which the SOC interprets its operational environment and identifies indicators of compromise. In the absence of sufficient visibility, neither proactive threat hunting nor effective reactive defence can be achieved.

Detection

Detection serves as the mechanism through which visibility is transformed into actionable security intelligence. It defines how a Security Operations Center (SOC) identifies potential security anomalies within an organization's monitored environment. Detection techniques range from basic anomaly-based alerting to advanced, context-aware rules that correlate multiple events across diverse data sources. Enrichment processes further enhance detection by adding contextual information to raw event data, thereby improving analytical accuracy and reducing the incidence of false positives. The output of the detection function is a set of findings that merit deeper examination during the investigation phase. The quality of these findings directly influences the overall efficiency of the SOC, as well-calibrated detection mechanisms reduce analytical noise and enable faster, more confident response actions. In this regard, detection constitutes both a technical and analytical capability, converting raw telemetry into meaningful security awareness.

Investigation

Investigation is the systematic process of validating, contextualizing, and interpreting detected anomalies. Its primary objective is to ascertain whether an event constitutes a genuine threat and to determine the appropriate course of action. Effective investigation relies on the capacity to correlate information from diverse data sources, employ suitable analytical tools, and integrate both automated processes and experts' analysis.

The investigation process aims to construct a structured understanding of:

- The nature and intent of the identified threat or anomaly
- The assets and systems affected
- The behavioral of the anomaly to these assets
- The potential or necessary remediation measures

Ultimately, investigation serves as the mechanism by which raw data is transformed into actionable knowledge. It converts signals into insight and insight into informed decisions, functioning as the pivotal link between detection and response.

React

The react function is responsible for addressing security events that require immediate containment or mitigation. It demonstrates the Security Operations Center's (SOC) ability to respond swiftly and decisively once a validated threat is identified. Typical reactive measures include isolating affected systems, blocking malicious connections, and initiating predefined remediation protocols. The effectiveness of the reaction phase is measured by its ability to limit damage and prevent escalation. By minimizing the interval between detection and containment, the SOC ensures operational continuity and reduces potential business impact.

Respond and Recover

The respond and recover domain encompasses structured activities aimed at restoring normal operations following an incident. While reaction primarily focuses on immediate containment, the response and recovery phase addresses the broader processes of resolution, remediation, and organizational learning. This phase incorporates coordinated incident response, forensic analysis, business continuity measures, and executing recovery, based on established recovery plans. Collectively, these functions ensure that technical restoration, organizational communication, and procedural follow-up are executed in a controlled, systematic, and well-documented manner.

Prevent

The prevention function is primarily concerned with minimizing exposure to prospective threats by mitigating vulnerabilities identified through prior Security Operations Center (SOC) processes. Preventive measures may encompass patch and configuration management, architectural modifications, user awareness programs, and the automation of system hardening procedures. These activities aim to reduce the attack surface and remediate known vulnerabilities before they can be exploited. By systematically leveraging SOC findings and operational observations, the prevention function effectively closes the feedback loop, ensuring that each security incident informs strategies that enhance the overall resilience and security posture of the organization.

Co-operation on Cyber Early Warning System and the Security Operations Center

In this chapter, CEWS data are linked to the empirically defined SOC process of the study. Drawing on the study's theoretical framework, the different phases of the SOC process outlined above benefit from early warning information, thereby facilitating proactive risk identification in so-called 'unknown unknown' situations.

Cyber Early Warning System (CEWS) is a value-adding piece to a workflow of Security Operation Center (SOC). In SOC environment the earlier coming attack is detected and the earlier it is mitigated, less resources are consumed at the defense against those attacks becomes. It is therefore important to prevent these attacks from materializing in first place. Any help for preventing the attack firsthand helps the workload of SOC. There should not be any overlapping between CEWS and SOC tasks, but merely CEWS should increase the SOC ability to proactively defend against different kinds of cyber-attacks. That is why CEWS must be integrated into each SOC environment in a way that is suitable for it and perform tasks that support the operation of the SOC, not to replace its different functions.

CEWS information can enhance every stage of the SOC process. Steering involves directing the SOC's capabilities at both operational and strategic levels, guided by CEWS insights. This information helps align SOC activities with

the evolving threat landscape. With CEWS information SOC can have more information on the development of the threat field and the prevailing state in the cyber operations environment. In this context, early warning information is wider scoped and aggregated information about actors and their TTP's in the cyber environment, ongoing phenomena, development trajectories of different subjects and for example early-stage warnings about dark market products, datasets or attack orders.

CEWS shapes the SOC's scope of visibility by prioritizing monitoring on critical areas or assets, while also complementing the SOC's internal threat intelligence. CEWS would increase the visibility of the SOC by producing cyber situational awareness and cyber threat intelligence outside the SOC environment. CEWS could also bring together situational awareness produced by itself, industries and experts in a similar way to, for example, sector-specific information sharing and collaboration network ISAC (Information Sharing and Analysis Center).

For detection, CEWS provides indicators of tactics, techniques, and procedures (TTPs), allowing detection rules to be fine-tuned for greater sensitivity and alignment with operational processes.

Investigation enables CEWS to remain viable despite imperfect accuracy by providing process-driven validation of weak signals. During this phase of the process, CEWS clarifies, for instance, the tools and methods commonly used by specific threat actors. In security analysis, the information is further enriched to anticipate potential developments.

CEWS also drives capability development, offering advanced insights that help evolve SOC operating models and response practices.

In the respond, recovery and preventing phases, CEWS enables organizations to effectively practice receiving and acting on early warning information. The Prevent phase emphasizes proactive measures, such as segmentation and other controls, where early CEWS alerts allow preventive actions that can stop attacks before they occur.

Although an organization's SOC primarily concentrates on operational and tactical activities to maintain cybersecurity situational awareness, an early warning system can also deliver strategic-level insights that support decision-making, particularly by enabling a deeper understanding of trend-based threat intelligence. A CEWS can direct SOC analysts' attention to specific areas of concern when it identifies correlations between the defended network and ongoing attack campaigns targeting a particular industry, supply chain, or similar context. Furthermore, a CEWS can help the SOC adapt its sensors and detection mechanisms to the tactics, techniques, and procedures of malicious actors, increasing sensitivity to relevant threats and improving the ability to detect and defend against such activities.

7. Conclusion

The cyber-physical environment integrates physical systems with digital technologies through networking, most notably the internet, which enables global connectivity of physical and digital systems. The internet is divided into the surface web, deep web, and dark web, each serving different purposes. Understanding these layers is important, as the Cyber Early Warning System (CEWS) collects data from all three.

It is important that an organization's situational awareness includes identifying critical digital elements within the environment, interpreting their significance, and understanding how they interrelate in the context of information security. It also involves anticipating future conditions and potential threats based on current data, enabling proactive rather than reactive responses. In this context, CEWS serves as a proactive cybersecurity capability designed to detect threats before, or at the earliest stages of an attack, allowing organizations to respond before substantial harm occurs. Unlike traditional security tools that generate alerts only once an attack is underway, CEWS focuses on identifying early indicators and conditions that could lead to future attacks. As a result, it is a vital component of an organization's Security Operations Center (SOC), enhancing situational awareness and supporting more effective risk assessment, particularly in complex and highly uncertain "unknown-unknown" cyber environments.

CEWS enhances all stages of the SOC process by aligning operations with the evolving threat landscape. The following phases of the SOC process have been identified: Steering, Visibility, Detection, Investigation, React, and Respond & Recover. SOC guides strategic and operational steering, focuses visibility on critical assets, and strengthens threat intelligence. CEWS improves detection through refined tactics, techniques, and procedures-based indicators, supports investigations by clarifying threat actor behaviours, and enriches security analysis to anticipate future risks. It also drives capability development and enables proactive response, recovery, and prevention by supporting early warning–driven actions that can stop attacks before they occur.

The SOC process of the study can be conceptualized as comprising the aforementioned components, each with a distinct role. These roles correspond to the "key elements" identified in the research question and are essential for supporting the use of CEWS information within the context defined by the study's framework.

In future work, our CEWS research team will focus on developing its early warning features. By integrating automated technologies such as Large Language Models (LLMs), Machine Learning (ML), and Natural Language Processing (NLP), CEWS can better leverage the vast amount of internet data in a rapidly changing environment. Manual analysis of this large-scale, multi-source information is not feasible for identifying early warning signals.

Abstract: Recently, the number of cyber threats has shown a rapid increase all over the world. Different public and private infrastructure organisations of a society have varying capabilities and resources to address these threats and protect themselves from their harmful impact. Among these sectors, critical infrastructures are most vulnerable as they hold valuable data, the protection of which is both crucial and expected from a societal perspective. As data protection relies on different capabilities, it is vital to understand what a specific capability a particular infrastructure sector and an individual company will need and can achieve. There is a wealth of high-quality information available on the best practices of cybersecurity, for example in frameworks like the ISO series and the National Institute of Standards and Technology Cybersecurity Framework (CSF) 2.0. These frameworks contain actions that are generally considered beneficial for any company but provide limited guidance on how individual controls translate into actionable capabilities in a specific organisational context. However, very few companies have the resources to implement all the controls presented in these frameworks to reach the highest maturity levels possible in cybersecurity. In these situations, it is crucial to maximise the benefits gained from any chosen action. In this paper, we investigate how a capability-based assessment model, developed originally for the defence domain, can be adapted to evaluate cybersecurity capabilities in the context of critical infrastructure and explore its performance when applied to a healthcare sector company. This model assesses capability gaps by comparing the current state with a target level capability and applies this approach to the cybersecurity context of a healthcare organisation. The general aim of our study is to support simpler and more effective decision-making when selecting the next cybersecurity upgrade or systemic improvement. In future research, we plan to extend this model to other critical infrastructure sectors and compare its performance and generalisability to these sectors.

Keywords: Cyber risk analysis, Cybersecurity capability gap, Decision support, Healthcare cybersecurity, Control action prioritisation

1. Introduction

In recent years cyber threats have increased both in volume and complexity. Rapid digitalisation across organisations has expanded the use of interconnected information systems, including cloud-based services, which in turn have broadened the landscape of cyber threats. While digitalisation enables greater efficiency, flexibility, and scalability, it also introduces new dependencies and potential vulnerabilities that organisations must manage. Yet these organisations across infrastructure sectors differ significantly in terms of their risk exposure and their capabilities to implement effective cybersecurity controls. Critical infrastructure organisations are no exception, for example, a healthcare organisation and a municipal water utility may both be classified as critical infrastructure, but they face distinct cybersecurity challenges and operational requirements. What such organisations have in common is that cybersecurity is not limited to technical functions alone but affects the entire organisation and requires informed decision-making beyond the IT domain.

To address these challenges, decision-makers have access to a wide range of high-quality guidance on potential actions that an organisation can take to improve its cybersecurity preparedness. This guidance is typically provided in the form of cybersecurity frameworks. Widely adopted frameworks include, for example, the ISO/IEC 27000 series and the National Institute of Standards and Technology CSF (National Institute of Standards and Technology, 2024). While these frameworks contain highly valuable guidance, their scope and level of detail make practical applications challenging. This is particularly the case for organisations that lack dedicated IT expertise or specialised IT teams, such as small and medium-sized enterprises (SMEs), where prioritising appropriate actions often becomes difficult to realise (El-Hajj and Mirza, 2024).

Within critical infrastructure sectors, healthcare is frequently targeted by cyber actors (ENISA, 2023). This is partly due to factors such as dynamic operational environment and frequent staff turnover. One major reason is also the fact that the primary function of the healthcare sector is to deliver services that support individual well-being and safety rather than cybersecurity. From a cybersecurity point of view, the healthcare industry faces multiple challenges such as the data availability requirements, as critical systems must operate

continuously. At the same time, sensitive patient data must be strongly protected against unauthorised access. Different laws and regulations affect the healthcare industry as well; one example is the General Data Protection Regulation (GDPR) and the national law about cybersecurity derived from the NIS2 directive. Social and healthcare organisations represent a critical infrastructure context in which capability gaps in cybersecurity can have significant operational consequences, while available resources for systematic improvements are often limited (Kruse et al., 2017).

Despite the demands outlined above, many organisations struggle to meet regulatory and recommended baselines of cybersecurity. This combination of limited resources, regulatory requirements, and insufficient current capabilities highlights the need for structured approach to cybersecurity capability assessment and prioritisation. Capability-oriented approaches have previously been applied to cybersecurity assessment using probabilistic and structural models, particularly to support reasoning about system-level security properties rather than individual controls (Sommestad et al., 2013). In this paper, we address these challenges by adopting a capability-based approach to support cybersecurity decision-making in resource-constrained organisational contexts.

2. Method

In this study, we apply a capability-based evaluation approach (Kuikka and Peltotalo, 2022) to assess cybersecurity within an organisation's IT department to analyse its ability to deliver cybersecurity outcomes that support organisational operations, data protection, and service continuity. Cybersecurity is treated as a socio-technical capability that emerges from the combined effect of technical, organisational, and operational measures. Our approach is based on a capability-gap formulation that structures expert judgement and supports prioritisation of cybersecurity improvements in resource-constrained environments.

Cybersecurity capability is decomposed into a finite set of sub-capabilities indexed by j, each of which is evaluated relative to a defined target level. The capability gap of sub-capability j is denoted as $g_j \in [-1, 1]$, where the sign and magnitude of g_j expresses the relationship between the current state and the target level. Positive values ($g_j > 0$) indicate that the current capability is below the target level, while negative value ($g_j < 0$) indicates that the current capability exceeds the target and the value of $g_j = 0$ corresponds to the target level being met. Then the vector of sub-capability gaps is defined as $G = (g_1, g_2, \ldots g_s)$.

In this study, a capability gap is defined as a signed normalised deviation from a predefined target level of a given cybersecurity sub-capability, where positive values indicate insufficient capability and negative values indicate capability exceeding the target. In earlier capability models applied to military contexts (Kuikka and Peltotalo, 2022), importance is implicitly embedded in the definition of capability as the likelihood of mission success. In the cybersecurity context considered in this study, capability is decomposed into multiple sub-capabilities supporting different organisational objectives, requiring the relative importance of achieving target levels to be represented explicitly. To support scenario comparisons, our method distinguishes between the initial capability gap and the capability gap after improvement actions. The initial capability gap of sub-capability j is denoted as g_j^0 and represents the state before any improvement actions are applied. The difference ($g_j^0 - g_j$) represents the reduction in the capability gap achieved through improvement actions.

Improvements in cybersecurity capabilities are characterised as functional enhancement actions rather than as separate technical systems. These actions can include changes to processes, improvements in configurations, updates to policies or procedures, training activities, or enhancements to existing tools and systems. Each improvement action i is assigned a positive weight $b_i > 0$ that reflects its relative importance, and its contribution to sub-capabilities is represented by the coefficient $c_{i,j}$, typically greater than or equal to zero.

Then the contribution of improvement action i to sub-capability j is first combined into a weight $w_{ij} = c_{ij} \cdot b_i$, which is then normalised as $p_{ij} = \frac{w_{ij}}{\Sigma_i w_{ij}}$, representing the relative influence of action i on sub-capability j. The capability gap is then allocated across actions as

$$d_{ij} = g_j \cdot p_{ij}. \quad (1)$$

This proportional decomposition allocates the post-action capability gap across improvement actions according to their relative contribution and ensures conservation of gaps, such that $\sum_i d_{i,j} = g_j$. For strategic decision-making, the overall cybersecurity capability gap after improvement actions is aggregated additively as $\sum_j g_j$. The aggregated gap is used as a comparative indicator for evaluating alternative improvement scenarios rather than as an absolute measure of cybersecurity performance.

Our approach includes also an economic interpretation based on the reduction of the capability gap. Expert-defined reference importance values $I_j \geq 0$ represent the potential consequences of insufficient capability. The expected consequence reduction achieved by improvement actions at the sub-capability level is defined as

$$L_j = \left(g_j^0 - g_j\right) I_j . \quad (2)$$

Reference importance values are defined through an initial expert evaluation and represent the relative consequences of achieving target capability levels within the organisational context. They remain constant across scenarios and are not re-evaluated for each set of improvement actions. Now, the aggregated consequence reduction across all the sub-capabilities is defined as the following sum

$$L = \sum_j \left(g_j^0 - g_j\right) I_j . \quad (3)$$

The initial gap g_j^0 represents the baseline scenario, while alternative scenarios are evaluated based on their ability to reduce positive capability gaps relative to this baseline. Conceptually, consequence-related measures combine normalised signed deviations from the target level with the relative importance of achieving that target, supporting comparison of improvement effectiveness without implying realised or future financial losses.

In addition to the expected consequence reduction, each improvement action is associated with an implementation cost (denoted by E_i) that is the relative effort required to perform functional improvement actions by the organisation and is evaluated independently of the importance and the capability gaps. Here, the notation E_i refers to the implementation effort associated with improvement actions and should not be confused with the importance values I_j, that are defined separately at the sub-capability level. The effort of implementation is evaluated using an ordinal scale with five qualitative categories (Low, Low/Medium, Medium, High, Very High). These categories capture aspects such as personnel workload, organisational effort, process changes, and operational complexity. To enable aggregation and comparative scenario analysis, the ordinal categories are mapped to numerical values on a linear scale. This mapping preserves the relative ordering of cost levels while avoiding assumptions about exact cardinal or monetary differences between categories. The resulting numerical cost values are therefore used as comparative indicators to support scenario evaluation and prioritisation, and they do not imply economic optimisation, precise cost estimation, or financial valuation of cybersecurity improvements.

Throughout the method cybersecurity capability is interpreted as an organisation's assessed ability to reach a defined target level, and all capability gaps represent deviations from this target, while cost and consequence considerations are introduced to support comparative interpretation of improvement scenarios. The method assumes that cybersecurity capability can be represented through a finite set of sub-capabilities and that capability gaps can be expressed as signed normalised deviations from a defined target level. The method is intended for comparative scenario analysis and decision support within IT departments and does not aim to predict cyber incidents, realised losses, or optimal investment portfolios.

3. Critical Infrastructure use Case

This use case study is based on a private healthcare organisation operating across multiple service locations. The organisation provides continuous nursing and care services and processes sensitive health-related data as well as other personally identifiable information. The company does not have a dedicated IT department or a separate cybersecurity unit. Due to the critical nature of its services, the organisation is classified as part of the national critical infrastructure under cybersecurity legislation derived from the EU NIS2 Directive. A significant number of individuals depend on the continuity of the services provided, placing high requirements on both operational resilience and data protection within a resource-constrained organisational setting.

3.1 Risk Register

Prior to this study, the organisation had established an IT risk register to document cybersecurity-related risks in its operating environment. Business risks and IT risks are assessed separately, and the IT risk register serves as the primary input for this use case study. It provides a structured and organisation-specific view of the current cybersecurity situation by identifying areas where existing capabilities are insufficient to manage recognised risks. The risk register categorises risks into strategic, operational, and tactical risks. Strategic risks include threats that could significantly disrupt operations or lead to regulatory intervention, such as reputational damage, compliance failures, or insufficient preparedness for critical system outages. Operational risks relate to disruptions in daily healthcare activities, including system unavailability and limited access to patient information. Tactical risks focus on people, processes, and technologies, such as inadequate access control,

weaknesses in offboarding procedures, delayed security updates, and ageing IT infrastructure. While these categories support structured risk management, individual risks may span multiple levels if left unaddressed over time.

3.2 Controls and Constraints

In this study, controls refer to improvement actions identified in the risk register that aim to mitigate recognised cybersecurity risks. These actions include organisational, procedural, and technical measures. A single control may address multiple risks across different risk categories, and its impact is not binary: implementing a control typically reduces the likelihood and/or impact of a risk rather than eliminating it entirely. Therefore, controls are treated as optional improvement actions of which the organisation must prioritise those that provide the greatest benefit relative to available resources. Controls are linked to cybersecurity capabilities through the risk register, in which identified risks are interpreted as indicators of existing capability gaps. Improvement actions are selected as means to strengthen the organisation's ability to manage these gaps.

Here, the case organisation faces significant constraints related to both financial resources and available expertise, as the IT and cybersecurity activities are largely outsourced and the organisation operates without a dedicated IT or cybersecurity leader. Responsibilities are distributed according to a "multiple hats" principle, limiting systematic evaluation of improvement options and increasing reliance on external service providers. Budgetary constraints further restrict the organisation's ability to implement multiple improvements simultaneously. These constraints directly shape cybersecurity decision-making by limiting which improvement actions are feasible. In practice, prioritisation is unavoidable, and suboptimal investment choices may result in limited improvement despite significant effort. This increases the need for structured decision-support methods that help organisations compare alternative improvement options and assess their potential impact before committing scarce resources.

4. Model and Application

In this use case, the organisation's IT risk register served as the primary input for the capability-based analysis. Identified cybersecurity-related risks were interpreted as indicators of insufficient cybersecurity capability rather than as isolated issues. Each risk was mapped to one or more cybersecurity sub-capabilities reflecting different aspects of cybersecurity, including governance, technical, organisational, and operational dimensions. This mapping was based on expert judgement and considered how each identified risk reflects underlying weaknesses in the organisation's ability to prevent, detect, or respond to cybersecurity-related events. The relationship between risks and cybersecurity capabilities is not one-to-one but many-to-many, meaning that a single risk may be associated with multiple capability gaps, while a single capability gap may contribute to several identified risks. For example, risks related to reputational damage and regulatory consequences were mapped to governance and response-related capabilities, whereas risks associated with data misuse and system disruptions were linked to access control, monitoring, and technical preparedness.

Figure 1 provides an overview of the capability-based evaluation workflow applied in this study. The process starts from the identification of cybersecurity-related risks and the assessment of current organisational capabilities, followed by the definition of improvement actions and the construction of alternative improvement scenarios. The scenarios are then evaluated by comparing their effects on capability gaps, expected consequence reduction, and implementation effort. The workflow is iterative in nature: after scenario comparison, decision-makers may return to earlier phases to refine assumptions, adjust improvement actions, or construct new scenarios before committing to control propositions. This iterative structure supports learning and refinement prior to resource allocation in resource-constrained organisational contexts.

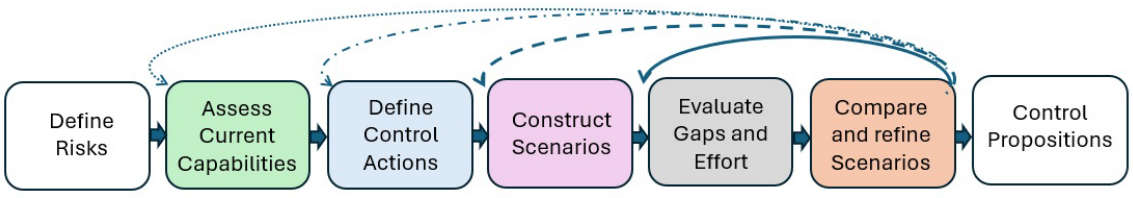

Figure 1: Capability-based workflow for cybersecurity improvement, from defining risks to scenario comparison and iterative refinement prior to control proposition

4.1 Defining Baseline and Capability Gaps

The current state of cybersecurity capability in the case organisation was defined based on the IT risk register at the time of assessment. The risk register was developed through expert judgement in collaboration with key organisational personnel and provides a documented, organisation-specific overview of identified cybersecurity-related risks. As such, it serves as a suitable and transparent starting point for the capability-based evaluation. Defining a target level is necessary to identifying capability gaps. In this case, the target level was defined as a contextually appropriate baseline level of cybersecurity capability, reflecting what can reasonably be expected from an organisation of similar size and resource constraints operating in the healthcare sector. As a fail-safe condition, the baseline level was anchored to regulatory and legal requirements, representing the minimum acceptable level of cybersecurity capability. In addition, best practices were considered only insofar as they were deemed realistic and achievable within the constraints of a small or medium-sized enterprise.

A capability gap is defined as an estimated deviation between the current state and the defined baseline level. Identified risks were interpreted as manifestations of insufficient cybersecurity capability, and the current state was compared against the baseline to determine the magnitude of each capability gap. Therefore, the capability gaps represent relative assessments of organisational capability shortfalls rather than risk probabilities or realised impacts.

The capability gaps are assessed using an asymmetric five-level expert-based scale reflecting deviations from the baseline level. The baseline level is defined as zero, with positive values indicating slight overperformance and negative values indicating increasing degrees of underperformance relative to the baseline. In practice, the scale takes the discrete values {−30, −20, −10, 0, +10}, where 0 represents the baseline level, −10 to −30 represent increasing shortfalls from the baseline, and +10 indicates marginal overperformance. This expert scale uses the opposite sign convention to the analytical formulation in Section 2, where positive values represent capability shortfalls. The discrete scale serves as a practical rating tool for expert assessment and scenario comparison. The resulting gap values are combined with the corresponding importance weights in the aggregation, as illustrated in Figure 2.

Control Actions for Scenario Evaluation	Weak cybersecurity governance	Reputational damage	Supply chain disruptions	Regulatory non-compliance	Poor data oversight	Lack of technical readiness	Data breach or manipulation	Post-attack reputational and regulatory impact	= Risks	Weak cybersecurity governance	Reputational damage	Supply chain disruptions	Regulatory non-compliance	Poor data oversight	Data breach or manipulation	Data breach or manipulation	Post-attack reputational and regulatory impact

Controls

Control actions

Figure 2: Excel-based application implementing the capability-based scenario evaluation method, illustrating the main model variables and their aggregation for comparative scenario analysis

4.2 Linking Improvement Actions to Capability Gaps

Improvement or control actions identified in the risk register are interpreted as measures aimed at addressing identified cybersecurity risks. As defined earlier, risks are understood as insufficient cybersecurity capability. Consequently, reducing a risk implies that one or more underlying capabilities related to that risk have been strengthened. Based on this interpretation, improvement actions are treated as capability-enhancing measures, as their implementation contributes to improving the organisation's ability to prevent, detect, or respond to cybersecurity-related events. Not all improvement actions contribute equally to reducing capability gaps in cybersecurity. Identified risks often consist of multiple dimensions, each of which may require specific actions

to be addressed. As a result, a single risk may be associated with several improvement actions, and the same improvement action may contribute to different risks and capabilities to varying degrees. By the same logic, implementing an improvement action does not necessarily result in uniform capability improvement across all related capability gaps. Even when the same action is applied, its effect on reducing different capability gaps may vary depending on how strongly the action addresses the underlying weaknesses reflected by each risk.

The model we apply here supports decision-making by making differences in the impact of improvement actions explicit. In practice, improvement options are often implicitly treated as equally important, particularly when using traditional risk registers where identified risks are addressed by corresponding control actions without explicitly considering their broader effect on organisational cybersecurity capability. By explicitly linking improvement actions to capability gaps, the model reveals interdependencies between actions and capabilities that may otherwise remain unrecognised. This is particularly relevant in small and medium-sized enterprises, where resource constraints are a well-documented challenge. Under such conditions, the model supports prioritisation by highlighting improvement actions that offer greater capability enhancement relative to the resources invested.

Unlike earlier military capability models, where importance is implicitly embedded in the probability of mission success, cybersecurity capabilities support multiple organisational objectives and therefore require explicit representation of relative importance. The scenario analysis demonstrates that capability-based evaluation can reveal differentiated and sometimes non-uniform risk reduction patterns across alternative improvement strategies, while still highlighting risks that are structurally sensitive to both high-impact and low-effort functional improvements. This supports the use of the proposed method as a comparative decision-support tool rather than as a predictor of individual incidents or losses.

4.3 Scenario Construction

In this study we constructed two comparative improvement scenarios to reflect decision-making under SME resource constraints, where only a limited set of actions can be implemented within a given planning cycle. In both scenarios, the number of selected improvement actions was limited to three. Scenario 1 (high-impact) prioritised actions expected to yield the largest reduction in importance-weighted capability gaps, using the product of the baseline capability gap and the corresponding importance value as the primary selection criterion. Scenario 2 (low effort) prioritised actions with lower implementation effort. In this study, the cost is interpreted as relative implementation effort rather than as a monetary value. The effort estimates are used solely for comparative scenario construction and do not represent actual financial costs or investment calculations. Implementation effort was assessed using an ordinal five-level scale (Low–Very High) and used only as a comparative indicator for scenario construction. The effort estimates do not represent monetary costs and are not used for economic optimisation; instead, they provide a pragmatic way to contrast “high-impact” versus “low-effort” improvement strategies within the same modelling structure.

4.4 Numerical use Case Results

An Excel-based application shown in Figure 2 implements a capability-based scenario evaluation method, highlighting the key model variables for comparative analysis. The risk categories and control actions used as inputs to the model are summarised in Tables 1 and 2, respectively.

Table 1: Risk categories

ID	Risk category
1	Weak cybersecurity governance
2	Reputational damage
3	Supply chain disruptions
4	Regulatory non-compliance
5	Poor data oversight
6	Lack of technical readiness
7	Data breach or manipulation
8	Post-attack reputational & regulatory impact

Table 2: Controls actions

ID	Control actions
1	Staffing adequacy
2	Backups
3	IAM usage
4	Supply chain
5	Data encryption
6	Information security guidance
7	Cybersecurity training
8	Crisis communication instructions & exercises
9	Cybersecurity management model
10	Monitoring and reporting

Figure 3 illustrates the effects of two alternative improvement scenarios on cybersecurity capability gaps across the risks shown on the horizontal axis. Scenario 1 (Figure 3a) represents a high-impact strategy, in which functional improvement actions are selected based on their overall effectiveness in reducing importance-weighted capability gaps. When multiple actions demonstrate comparable effectiveness, preference is given to those that contribute most strongly to the product of the capability gap and importance (see Table 3). The selected actions address personnel adequacy, crisis communication guidance and exercises, and the establishment of a cybersecurity management model. In Scenario 1, the gap reductions are unevenly distributed across risks, with particularly pronounced reductions for risks associated with weak cybersecurity governance and organisational preparedness (Risk 1). This reflects the strong alignment between the selected actions and the underlying capability gaps contributing to that risk rather than a uniform reduction across all risk areas.

Scenario 2 (Figure 3b) represents a low-effort improvement strategy, where actions are selected primarily based on lower implementation effort while applying the same capability-based aggregation logic. Overall reductions are more moderate and more evenly distributed; however, a notable reduction is again observed for Risk 1. This indicates that certain risks are structurally sensitive to relatively feasible functional improvements, even when actions are not chosen to maximise overall impact.

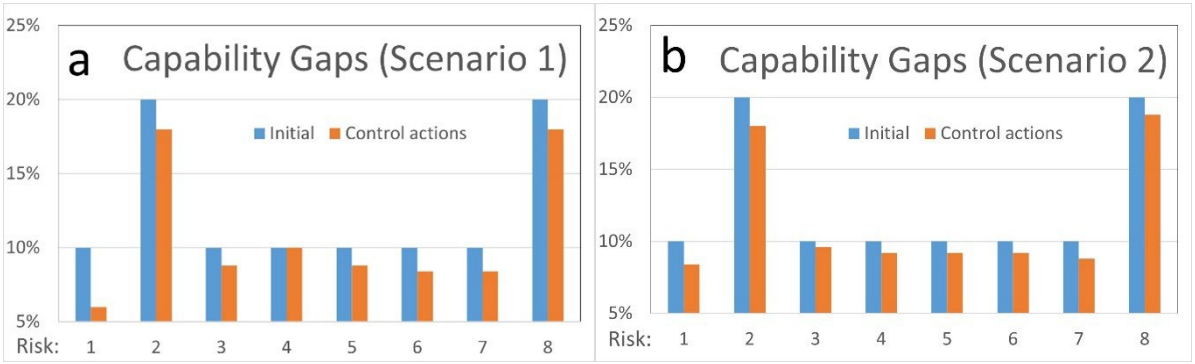

Figure 3: a) Scenario prioritising maximum reduction of importance-weighted cybersecurity capability gaps through selected functional improvement actions. b) Scenario prioritising low implementation effort while applying the same capability-based aggregation logic for cybersecurity improvement

The results show that importance-weighted capability gaps are reduced to different extents depending on the prioritisation strategy, with high-impact actions yielding the largest overall reduction and low-effort actions still providing meaningful improvement relative to the baseline. In Table 3, the quantity $\sum_j I_j g_j$ represents the residual importance-weighted capability gap, where lower values correspond to greater improvement from the baseline.

Table 3: Importance values I_j and products of importance and residual gap values $I_j g_j$ for the two Scenarios 1 and 2. For comparison in Scenario 0, no improving actions are implemented

Risk		1	2	3	4	5	6	7	8	
I_j	All scenarios	0.95	1	0.9	0.95	1	0.9	1	1	$\sum_j I_j g_j$
$I_j g_0$	Scenario 0	0.095	0.200	0.090	0.095	0.100	0.090	0.100	0.200	97.0 %
$I_j g_j$	Scenario 1	0.057	0.180	0.079	0.095	0.088	0.076	0.084	0.180	83.9 %
$I_j g_j$	Scenario 2	0.080	0.180	0.086	0.087	0.092	0.083	0.088	0.188	88.4 %

4.5 Interpreting Scenario Results

The scenario results are intended for comparison rather than as exact measures of cybersecurity performance. Because the effects of improvement actions are allocated proportionally based on their links to different capabilities, the same action may reduce some capability gaps more than others. As a result, some capability gaps are expected to remain after the improvements. Therefore, the results show how different prioritisation choices affect which capability gaps are reduced and to what extent.

From the decision-support perspective, our method helps to make trade-offs visible between (i) improvement actions that provide broader capability gains and (ii) the effort required to implement those actions. As shown in Table 3, the baseline scenario (Scenario 0) yields an importance-weighted capability gap of 97.0%. Scenario 1 reduces this value to 83.9%, representing the largest overall improvement when selecting three actions based on high impact, whereas Scenario 2 achieves a more moderate reduction to 88.4% when selecting three actions with the lowest implementation effort. This confirms that prioritising actions based on high-impact strategy of Scenario 1 leads to greater overall capability gap reduction of 13.5% than the low-effort strategy still leading to a meaningful reduction of 8.9% relative to the baseline.

5. Conclusion

In this study we investigated how a capability-based evaluation model, originally developed in a military context, can be adapted to support cybersecurity decision-making in a resource-constrained critical infrastructure organisation. The model was applied to a healthcare company using an existing IT risk register as the primary input to assess capability gaps and evaluate alternative improvement scenarios.

The results indicate that the model provides a structured and transparent way to reason about how different improvement actions contribute to cybersecurity capabilities and how limited resources can be prioritised more systematically. In particular, the scenario analysis helped to distinguish between high-impact and low-effort improvement strategies and demonstrate that capability gaps are reduced in non-uniform ways depending on the prioritisation logic applied. This supports the use of the model as a comparative decision-support tool rather than as an absolute measure of cybersecurity performance.

Several limitations should be considered when interpreting the findings. First, the evaluation was conducted as a single use case study within the healthcare sector, which could limit the method's generalisability to other organisations or critical infrastructure domains. Second, representatives of the use case organisation did not directly participate in the modelling or scenario construction. The analysis relied on previously produced organisational material and expert judgement, which ensured contextual realism but limited direct validation from decision-makers. Third, the assessment of capability gaps, control impacts, and scenarios was inherently subjective and based on a single evaluator. Finally, the implementation effort estimates used in the scenarios were intentionally coarse and context-specific, supporting relative comparison rather than precise economic evaluation.

In the future we will apply the proposed approach to multiple organisations and across different critical infrastructure sectors to evaluate its generalisability and sector-specific applicability. Involving multiple evaluators and organisational stakeholders would further support validation and reduce subjectivity. In addition, future development could explore the use of artificial intelligence–based methods to support estimation of control impacts, sensitivity analysis, and scenario generation. Such extensions could lower the threshold for applying the model in practice while preserving its role as a comparative decision-support tool.

Ethics declaration: This study did not involve the collection or processing of personal data. The case material was fully anonymised and contained no identifiable information about individuals or the organisation. Ethical approval was therefore not required for this study.

AI declaration: AI tools were used to support language refinement and clarity of expression. All analytical content, modelling decisions, interpretations, and conclusions were produced by the authors.

Abstract: This paper presents a Bayesian-driven serious game designed to support human-centered anti-phishing training through explainable artificial intelligence and adversarial gameplay. As phishing attacks increasingly leverage personalization and AI-assisted social engineering, traditional training approaches and opaque detection systems offer limited support for developing strategic awareness and decision-making under uncertainty. The proposed framework addresses this gap by combining Bayesian explainability with an interactive, adversarial learning environment. The serious game was implemented in a military academy context and centers on a sandboxed anti-phishing platform powered by a Bayesian Network. Participants are tasked with crafting targeted phishing emails for simulated victims using social media-derived contextual information. Each email submission is analyzed by the Bayesian engine, which outputs both a probabilistic phishing likelihood score and an explanation highlighting the linguistic features that contributed most strongly to the classification. Learners then iteratively revise the same email to reduce detectability, effectively attempting to "fool" the system while preserving semantic intent. Evaluation was conducted using two complementary data sources: interaction logs from the game and a post-activity questionnaire. The results suggest that integrating explainable Bayesian models into adversarial serious games can effectively enhance phishing awareness, strategic thinking, and sensitivity to uncertainty. The study highlights the potential of explainable AI not only as a defensive mechanism, but also as a powerful educational tool in cybersecurity training.

Keywords: Serious game, Explainability, Bayesian inference, Phishing

1. Introduction

The contemporary cybersecurity landscape is characterized by a continuous increase in the complexity, adaptability, and targeted nature of cyber threats (Masunda, 2025). As attackers increasingly leverage artificial intelligence and automation technologies, cyberattacks are evolving from generalized and predictable actions into strategically designed operations that exploit human, cognitive, and social vulnerabilities (Infosecurity Magazine, 2025). Within this context, phishing attacks constitute one of the most prevalent and effective forms of cyber threats, as they bridge the technical and human layers of security (Mutlutürk et al., 2024).

The detection of phishing attacks no longer relies on obvious technical flaws or generalized patterns (Kavya & Sumathi, 2025). Instead, modern phishing campaigns exploit personalized content, social context, and linguistic nuances to construct persuasive narratives that can bypass both human judgment and automated detection systems (Push Security, 2025). Consequently, the prevailing approach to phishing detection, which emphasizes technical features and statistical patterns, remains effective in certain scenarios but exhibits notable limitations at both operational and educational levels. From an educational perspective, users often interact with anti-phishing systems as black-boxes, receiving a final decision or risk score without meaningful insight into how and why a message has been classified as suspicious (Calzarossa et al., 2025). This lack of transparency constrains the development of strategic thinking, as learners are unable to associate specific linguistic or social design choices with corresponding risk assessments (Rjoub et al., 2023). Such limitations highlight the need for explainable models that incorporate qualitative content analysis and decision justification, thereby enhancing user understanding and trust.

Effective education for addressing phishing threats therefore requires a shift from the mere recognition of technical indicators toward an understanding of uncertainty, causality, and the adaptive behavior of attackers (Lappas & Karampelas, 2024). One approach aligned with this perspective is the cultivation of probabilistic reasoning (Huang & Zhu, 2018; Rjoub et al., 2023), which supports decision-making in environments characterized by uncertainty, an essential competence in modern cybersecurity contexts.

In this context, Explainable Artificial Intelligence (XAI), and particularly Bayesian approaches, provide a strong theoretical and pedagogical foundation for cybersecurity education. Bayesian Networks enable the quantification of uncertainty and the modeling of causal relationships through conditional probabilities, making transparent how individual message features influence the overall phishing risk assessment (Pearl, 1988; Calzarossa et al., 2025). This capability is especially critical in educational environments, where understanding the decision-making process is as important as the final outcome, as it fosters strategic thinking skills and trust in automated systems (Rjoub et al., 2023).

Building upon these considerations, the present study developed a purpose-built anti-phishing tool designed explicitly for educational use. The tool is based on a Bayesian Network and provides not only a probabilistic phishing risk estimation but also interpretable feedback regarding the linguistic and contextual features that contributed to the assessment. The educational approach is further strengthened through the integration of adversarial game dynamics. The application of adversarial game dynamics emphasizes learner engagement in simulations that reveal attacker strategies and encourage the adoption of corresponding counter-strategic reasoning (Prebot, Du, & Gonzalez, 2023; Shashkov et al., 2023). Through this process, participants gain experiential insight into both social engineering strategies and the capabilities and limitations of anti-phishing systems (Pawlick et al., 2019).

Accordingly, this study proposes a holistic educational framework that combines Bayesian explainability and adversarial gaming dynamics for phishing awareness and defense training. The primary contributions of this work are summarized as follows:

- Highlighting the limitations of conventional anti-phishing tools with respect to qualitative message analysis.
- The development of an educational Bayesian anti-phishing system with built-in explainability.
- The investigation of the role of adversarial serious games in fostering strategic thinking and uncertainty awareness in cybersecurity contexts.

Unlike existing phishing training tools, this work exposes the internal probabilistic reasoning of the detection system and positions the learner in an adversarial optimization loop.

To guide the reader, the remainder of this paper is structured as follows. Section 2 presents the theoretical background, covering Explainable AI in cybersecurity, Bayesian Networks and adversarial game theory. Section 3 formulates the research problem and identifies gaps in the existing literature. The proposed educational framework, system design, evaluation methodology and results are described in Section 4. Finally, Section 5 discusses the findings and outlines directions for future research.

2. Theoretical Framework

2.1 Explainable AI (XAI) in Cybersecurity

Explainable Artificial Intelligence (XAI) encompasses methods that render the decisions of AI systems transparent and interpretable, enabling users to understand not only system outputs but also the reasoning processes underlying them (Calzarossa, Giudici, & Zieni, 2025). In cybersecurity, explainability is particularly important, as automated decisions directly affect trust, situational awareness, and operational responses to threats.

Within phishing detection, traditional machine learning approaches often operate as black-boxes, providing users with a binary classification or risk score without insight into the contributing factors. This opacity limits both user trust and educational value, as learners are unable to associate specific linguistic or contextual cues with phishing risk (Rjoub et al., 2023). XAI techniques address this limitation by exposing influential features or causal relationships, allowing users to reflect on why a message is considered suspicious.

Feature-attribution methods such as Local Interpretable Model-agnostic Explanations (LIME) have been used to highlight influential words or structural patterns in phishing emails (Ribeiro, Singh, & Guestrin, 2016). Probabilistic approaches, particularly Bayesian models, further enhance explainability by explicitly representing uncertainty and causal dependencies among features. Such models enable users to observe how individual elements contribute to the overall risk assessment, making them well suited for educational contexts where understanding decision logic is as important as detection accuracy.

Despite these advantages, applying XAI in education introduces challenges. Overly complex explanations may overwhelm learners, while overly simplified explanations risk misrepresenting system behavior (Mellon &

Worrell, 2023). Consequently, educational XAI systems must balance interpretability, realism, and cognitive load to effectively support learning.

2.2 Bayesian Networks and Uncertainty

Bayesian Networks (BNs) are probabilistic graphical models that represent causal relationships between variables using directed graphs and conditional probability distributions (Pearl, 1988). Their defining strength lies in their capacity to model uncertainty explicitly, allowing probabilistic inference in environments characterized by incomplete information.

In cybersecurity, Bayesian Networks have been applied to risk assessment, intrusion detection, and attack modeling by integrating heterogeneous indicators into coherent probabilistic estimates (Xie et al., 2010; Wei & Dong, 2025). Within phishing analysis, BNs can capture how linguistic cues, contextual signals, and behavioral patterns jointly influence the likelihood that a message constitutes a phishing attempt.

From an educational perspective, Bayesian Networks offer distinct pedagogical advantages. By exposing conditional dependencies and posterior probability updates, they support the development of probabilistic reasoning and decision-making under uncertainty. Learners can observe how small changes in input features propagate through the model, altering risk assessments in a transparent and interpretable manner. This aligns closely with educational goals in cybersecurity, where uncertainty awareness and causal reasoning are critical competencies (Rjoub et al., 2023).

However, educational use of Bayesian Networks requires careful abstraction. Highly complex models may obscure learning objectives, while simplified models must still preserve meaningful causal structure. Prior work has shown that scenario-specific Bayesian models can effectively balance interpretability and realism, particularly when designed explicitly for training rather than operational deployment (Lappas et al., 2025a; Lappas et al., 2025b).

2.3 Adversarial Game Theory in Cybersecurity

Game theory provides a formal framework for analyzing strategic interactions between competing agents. In cybersecurity, adversarial game theory models the dynamic interaction between attackers and defenders, each adapting strategies under uncertainty and resource constraints (Huang & Zhu, 2018). Rather than static classification problems, cybersecurity challenges often involve iterative adaptation, deception, and counter-strategy.

Educational applications of adversarial game theory typically employ role-based simulations, where learners assume attacker or defender perspectives to experience strategic trade-offs firsthand (Prebot, Du, & Gonzalez, 2023). Such simulations foster deeper understanding of attacker behavior, system vulnerabilities, and the limitations of defensive mechanisms.

When combined with explainable probabilistic models, adversarial games can transform detection systems into interactive learning environments. Learners do not merely observe outcomes but engage in strategic adaptation informed by transparent feedback. This approach supports the development of adversarial reasoning, perspective-taking, and adaptive decision-making, skills that are essential in contemporary cybersecurity practice (Pawlick et al., 2019; Shashkov et al., 2023).

3. Problem Statement

The integration of Explainable Artificial Intelligence (XAI), Bayesian Networks, and adversarial game theory offers a promising foundation for cybersecurity education. XAI enhances transparency in algorithmic decision-making, enabling learners to understand why specific messages are classified as phishing. Bayesian Networks complement this capability by providing a formal mechanism for quantifying uncertainty and modeling causal relationships among linguistic and contextual features. Adversarial game theory further extends this framework by positioning learners as strategic agents who must adapt their behavior based on probabilistic feedback (Huang & Zhu, 2018; Rjoub et al., 2023).

This combined perspective moves beyond traditional cybersecurity training approaches, which often emphasize theoretical instruction or isolated simulations. Instead, it supports learning environments where explanation, uncertainty reasoning, and strategic interaction are tightly coupled. Within such environments, learners can explore how their decisions influence detection outcomes, reflect on system behavior, and iteratively refine their strategies.

Despite advances in these individual domains, significant gaps remain in the existing literature. Most XAI research in cybersecurity focuses on technical interpretability methods, with limited attention to their pedagogical integration and impact on learner decision-making (Rjoub et al., 2023). Bayesian Networks are predominantly employed for operational risk assessment and detection, rather than as interactive educational tools that allow learners to experiment with probabilistic models and uncertainty-driven scenarios (Frigault & Wang, 2008; Xie et al., 2010). Similarly, while adversarial game theory has informed defensive and offensive cybersecurity strategies, its systematic application in educational settings, particularly in combination with explainable probabilistic models, remains underexplored (Huang & Zhu, 2018; Pawlick et al., 2019).

These limitations highlight the need for an integrated educational framework that unifies explainability, probabilistic uncertainty modeling, and adversarial interaction. Research Part

3.1 Design and Implementation of the Educational Intervention

The educational intervention was structured as a concise, multi-phase instructional sequence, explicitly designed to operationalize theoretical constructs from explainable artificial intelligence, Bayesian probabilistic reasoning, and adversarial game dynamics within a cybersecurity training context. The sequence comprised:

- Theoretical lectures introducing the taxonomy of phishing attacks and the psychological underpinnings of social engineering techniques.
- Conceptual exposition of Bayesian networks, focusing on their capacity to model uncertainty and causal relationships in automated decision-making systems.
- Experiential learning through a hands-on session utilizing the custom-developed serious game platform.

The serious game functioned as the integrative nexus where abstract theoretical principles were translated into actionable skills. Within this environment, participants engaged in a series of scaffolded activities, including:

- Bayesian reasoning tasks: Interpreting probabilistic phishing scores, analyzing the influence of specific linguistic and contextual features, and exercising decision-making under uncertainty.
- Adversarial, game-based decision-making: Iteratively modifying phishing strategies in direct response to transparent, explainable feedback from the Bayesian detection software.
- Reflective practice: Critically comparing human intuition with algorithmic judgment, thereby fostering metacognitive awareness of both strengths and limitations in human-AI collaboration.

A central pedagogical emphasis was placed on elucidating how subtle linguistic modifications propagate through the probabilistic model, altering posterior risk assessments and detection outcomes. This approach foregrounded the dynamic interplay between attacker adaptation and defender detection logic.

The intervention targeted the following learning objectives:

- To cultivate a nuanced understanding of uncertainty and explainability in automated cybersecurity decision systems.
- To develop adversarial and strategic thinking by anticipating and circumventing detection mechanisms.
- To enhance awareness of social engineering tactics, moving beyond superficial indicators to deeper, context-sensitive threat analysis.

By simultaneously exposing participants to both the attack surface and the internal logic of the detection system, the framework advanced a human-centered, explainable approach to phishing defense. This design not only demystified the operation of probabilistic classifiers but also empowered learners to reason strategically about both offensive and defensive dimensions of cybersecurity.

3.2 Research Context

The presented work adopts a design-based case study approach within a higher-education cybersecurity training context. It was held on October 20, 2025, at the Polish Air Force University, on October 28, 2025, at the Portuguese Air Force Academy and on December 5, 2025, at the Hellenic Air Force Academy as part of the "Cyber Warfare" training within the "European Union Military Erasmus" program. A total of 126 students from six different European countries, aged 19 to 21, participated in the training. All participants were cadets from military academies. The module spanned six training hours at each place.

Rather than evaluating a static detection model, the focus is on the human-algorithm interaction and on how explainable probabilistic feedback can support adversarial reasoning and cybersecurity awareness. The serious game was deployed as part of a structured educational intervention and served both as a training instrument and as a data collection mechanism for observing participant behavior under uncertainty.

The study explores how learners interpret, exploit, and adapt to Bayesian phishing detection mechanisms when explicitly exposed to their internal reasoning.

3.3 Framework design

The proposed educational framework synthesizes Bayesian explainability with adversarial game dynamics, fostering an environment where learners alternate between attacker and defender roles. This dual-role approach operationalizes theoretical constructs from explainable AI and game theory, enabling participants to experience both the strategic creation of phishing messages and the probabilistic evaluation of such attacks.

At the core of the system are three interdependent modules:

1. Scenario & Target Profiling Module: participants are provided with a simulated victim profile constructed from fictionalized social media data, closely emulating realistic open-source intelligence (OSINT) sources commonly exploited in social engineering. More specifically, the profile depicted a German fighter pilot who expressed a passion for running and a keen interest in the military aviation history. The individual also disclosed specific dietary habits and preferences for particular brands of running shoes. Frequent references were made to a close friend named Josh and to the individual's daughter. All such information was publicly accessible through the designated social media platform, thereby grounding the exercise in authentic adversarial contexts and supporting the development of targeted attack strategies by the participants (figure 1).

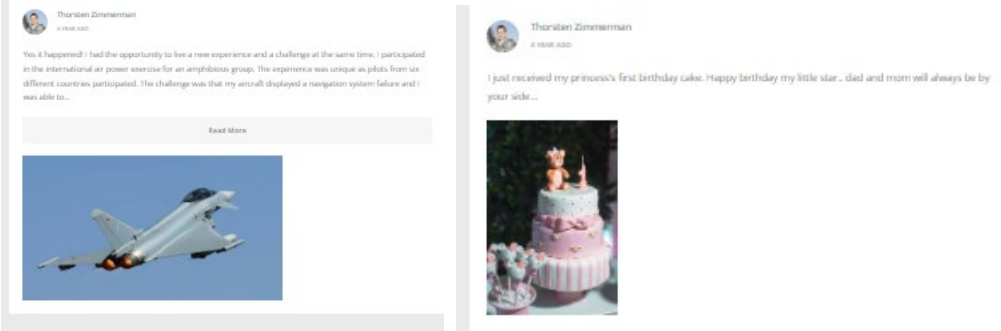

Figure 1: Images from the hypothetical person's social media profile

2. Bayesian Anti-Phishing Software: In the context of the Bayesian Anti-Phishing Software, submitted emails were evaluated by a Bayesian Network-based classifier, which provided both a probabilistic phishing likelihood score, quantifying the risk associated with each message and an interpretable explanation highlighting the lexical and contextual features most influential in the classification process. Each detected feature was mapped to a corresponding node within the Bayesian network, facilitating the propagation of uncertainty and modeling conditional dependencies between linguistic cues and phishing risk.

The construction of the Bayesian network was informed by qualitative data collected over the previous years, during which the same phishing scenario and target profile were used in instructional settings (Lappas & Karampelas, 2023). Emails authored by participants in these earlier cohorts were systematically analyzed and categorized according to the persuasive elements and strategies employed to attract the target. The frequency and distribution of these elements were quantified, enabling the derivation of conditional probabilities for the network. As a result, the Bayesian model was specifically tailored to predict the likelihood that an email would constitute a phishing attempt within this scenario. The network was implemented in Python and programmed to recognize keywords within the email text that corresponded to the semantic meaning of each node. When such keywords were detected, the respective node was activated, thereby influencing the overall risk assessment produced by the model (figure 2).

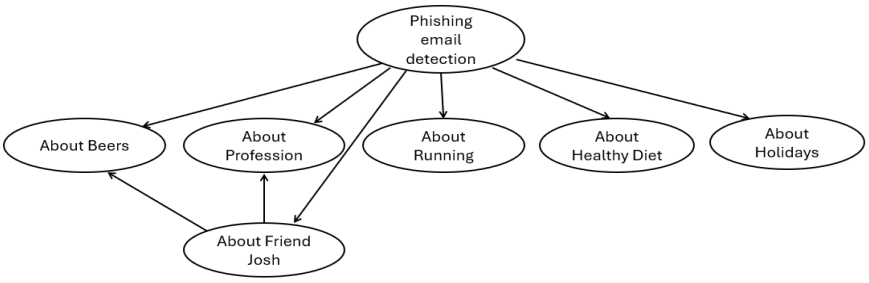

Figure 2: The bayesian network used in the educational framework

3. Explainability & Feedback Module: The system transparently exposes detected keywords and their respective impact on posterior probabilities, transforming the classifier from a traditional black-box filter into an interactive, explainable adversarial opponent. This module enables learners to iteratively refine their strategies based on actionable feedback, reinforcing the link between feature manipulation and detection outcomes.

Figures 3 and 4 illustrate a representative example of adversarial adaptation, showing how a participant iteratively revised a phishing email in response to explainable Bayesian feedback, resulting in reduced detection probability through targeted lexical modifications while preserving semantic intent. Furthermore, semantic similarity analysis between the two email versions yielded a high score of 0.965, indicating that the core message and communicative intent were preserved despite localized linguistic modifications. This example demonstrates the capacity of participants to interpret explainable Bayesian feedback and engage in adversarial reasoning. Rather than resorting to superficial deletion of flagged terms, the trainee employed strategic substitutions and contextual adjustments, successfully reducing the detectability of the phishing attempt while maintaining message coherence. Such behavior exemplifies the adversarial learning objectives of the proposed framework, wherein learners internalize the probabilistic logic of automated detection and adapt their strategies accordingly.

Figure 3: Image from the anti-phishing software that the trainee was viewing in the first effort

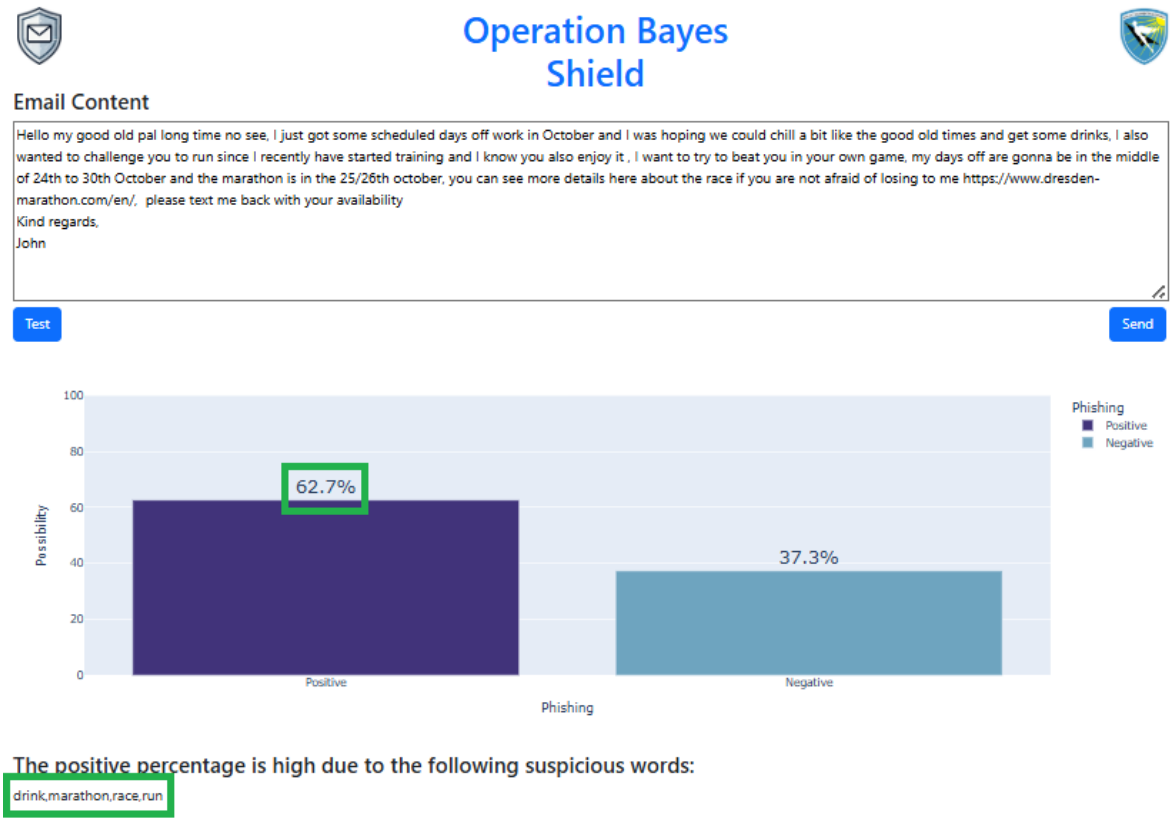

Figure 4: Image from the anti-phishing software that the trainee was viewing in the second effort

3.4 Scenarios and Roles

The serious game scenario is designed to authentically simulate a targeted spear-phishing attack, immersing participants in realistic adversarial dynamics. Learners alternate systematically between two roles (figure 4):

- Attacker: Participants craft phishing emails tailored to the simulated target's interests, behavioral patterns, and social connections, leveraging open-source intelligence data provided by the system.
- Defender: Participants analyze how the Bayesian anti-phishing software evaluates their crafted messages, interpreting the system's probabilistic risk assessments and the rationale behind flagged features.

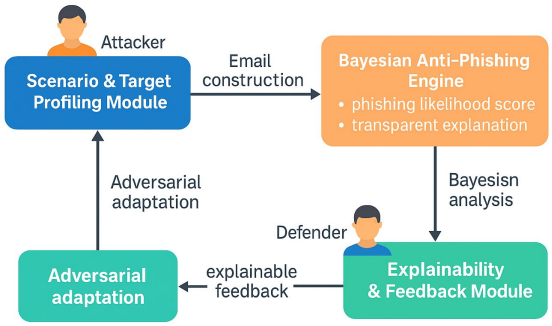

Figure 4: Roles in Bayesian Anti-phishing Serious Game

A key instructional constraint requires participants to iteratively revise a single email instance, maintaining semantic continuity while strategically modifying linguistic and contextual elements. This design choice discourages superficial keyword removal and instead promotes meaningful adversarial adaptation, mirroring real-world attacker behavior.

To further enhance strategic engagement, the number of permissible resubmissions is deliberately limited. This introduces a layer of decision-making pressure, compelling learners to reflect critically on each modification and to anticipate the evolving detection logic of the Bayesian system.

Through this dual-role, iterative process, the scenario operationalizes the theoretical principles of adversarial game theory and explainable AI, fostering both offensive and defensive cybersecurity competencies within a controlled, feedback-rich environment.

3.5 Results of Trainee Submissions

The analysis of participant submissions within the serious game framework was conducted across three complementary dimensions: (a) changes in phishing detection probability between successive email revisions, (b) modification of detected keywords across iterations, and (c) semantic similarity between initial and revised email versions.

Quantitative results revealed a consistent reduction in the Bayesian phishing probability between the first and second submissions (from 55.36% to 51.28%), indicating effective adversarial adaptation following explainable feedback. The probability stabilized in the third submission, suggesting convergence toward an optimal strategy. This trend demonstrates that learners successfully internalized the probabilistic feedback and adapted their strategies to minimize detectability, fulfilling a core objective of the educational framework.

A qualitative examination of the detected keywords further substantiates this interpretation. Rather than simply removing highlighted terms, participants engaged in targeted lexical adaptations, replacing flagged keywords with semantically related or contextually neutral alternatives. This behavior reflects adversarial reasoning aligned with realistic attacker strategies, whereby the core message is preserved while overtly suspicious signals are minimized. The evolution of keyword sets across submissions illustrates that learners internalized which categories of terms (e.g., urgency, reward, brand-related cues) significantly contributed to higher phishing risk assessments.

Semantic similarity analysis supports these findings, with similarity scores between initial and revised emails remaining consistently high (mean similarity 0.886 between first and second, and 0.954 between second and third submissions). This indicates that participants preserved the core intent and communicative purpose of their emails, opting for strategic linguistic refinement rather than superficial or trivial content removal. Evaluation of the Educational Intervention

To assess the pedagogical impact of the intervention, participants completed a post-activity questionnaire using a 5-point Likert scale (1 = strongly disagree, 5 = strongly agree). The overall mean score across all items was 4.28, indicating a highly positive evaluation of the learning activity. The internal consistency of the scale was excellent (Cronbach's $\alpha = 0.96$), supporting the reliability of the findings.

The results demonstrate substantial learning gains. For example, 84.8% of participants agreed or strongly agreed that they understood phishing techniques better after playing the game, while 94.0% reported increased ability to recognize social engineering tactics in emails. Similarly, 87.8% felt that the game helped them understand how attackers craft deceptive messages, and 81.8% considered the game a useful method for learning about phishing. Notably, 90.9% believed that this activity would benefit future students, and 84.8% agreed that it is more effective than lecture-only learning.

Regarding system transparency and explainability, 78.8% agreed or strongly agreed that the detected keywords made the system's reasoning transparent, and 81.8% understood why the system changed the phishing probability. Furthermore, 78.8% reported that the game helped them understand how automated filters make decisions.

General satisfaction was high, with 84.8% expressing overall satisfaction with the activity and 84.8% stating they would recommend the game to others. Areas with higher neutrality (e.g., ability to identify highly personalized phishing or clarity of feedback) suggest opportunities for further improvement.

In summary, the intervention was perceived as highly effective in enhancing both conceptual understanding and practical skills related to phishing detection, while the integration of explainable AI elements contributed to learners' confidence and strategic thinking.

3.6 Discussion

The study demonstrates the pedagogical value of integrating explainable Bayesian models within adversarial serious games for cybersecurity education. Observed reductions in phishing probability and subsequent stabilization indicate that participants adopted informed strategies rather than relying on trial-and-error, reflecting an internalization of the Bayesian model's logic and realistic attacker adaptation.

High semantic similarity scores confirm that learners preserved message intent while making targeted lexical adjustments, avoiding superficial keyword deletion. This suggests the development of strategic manipulation skills grounded in understanding, a key educational objective.

Questionnaire responses reinforce these findings, highlighting improved comprehension of phishing techniques and the probabilistic reasoning behind automated detection systems, addressing a gap in traditional training approaches. Explainable feedback acted as a cognitive scaffold, transforming the detection system into an interactive learning counterpart and fostering trust and strategic reasoning.

Overall, the combination of adversarial role-play and transparent probabilistic feedback cultivates critical competencies such as uncertainty reasoning, attacker–defender perspective-taking, and adaptive decision-making, skills essential in cybersecurity environments facing AI-driven threats.

One limitation relates to the question of learning transfer.. The present study assessed strategic adaptation and uncertainty reasoning within a sandboxed, simulated phishing scenario, yet did not measure whether these competencies translate to real-world detection of unsolicited phishing attempts. The extent to which learners generalize adversarial understanding to authentic environments remains an open empirical question.

On the other hand, a potential concern associated with adversarial training approaches is the dual-use nature of the skills developed: participants learn techniques for crafting more effective phishing emails. This mirrors established practices in cybersecurity education, where offensive methodologies, such as penetration testing and red-team exercises, are routinely taught to cultivate defensive competence. In this context, the controlled environment, limited scope of the scenario, and absence of real operational impact ensure that the adversarial component serves strictly educational purposes.

Future work may include developing the framework in more diverse student populations, including non-military academic settings or professional training environments where it can offer more relevant information and generalizability of conclusions.

4. Conclusion

This paper introduced a Bayesian-driven serious game for anti-phishing training that integrates explainable AI principles with adversarial game dynamics. By exposing learners to both the construction of phishing emails and the transparent reasoning of a Bayesian detection system, the proposed framework advances a human-centered approach to cybersecurity education.

Empirical results from interaction logs and post-activity evaluation indicate that participants were able to strategically adapt their behavior in response to explainable probabilistic feedback. The observed reduction in phishing detection probability across submissions, combined with high semantic similarity between email versions, demonstrates meaningful adversarial learning rather than trial-and-error behavior. Moreover, participant feedback confirms that the explainability of the Bayesian model played a central role in enhancing understanding, confidence, and trust in automated detection mechanisms.

From a cybersecurity perspective, the study contributes evidence that explainable probabilistic systems can serve not only as defensive tools, but also as effective educational instruments for developing strategic thinking and uncertainty awareness. The findings suggest that exposing users to the internal logic of detection mechanisms may improve long-term resilience against sophisticated, AI-assisted phishing attacks.

Future work will focus on extending the framework to additional attack scenarios, incorporating longitudinal measurements, and exploring how learner-generated data can further refine Bayesian detection models. Overall, the proposed approach demonstrates that gamified, explainable Bayesian systems offer a promising pathway for advancing human-centered cybersecurity training.

Ethics Declaration: This study did not involve the collection of personal or sensitive data and was conducted within a controlled educational setting. Therefore, formal ethical clearance was not required. All participants were informed about the purpose of the activity and consented to the use of anonymized data for research purposes.

AI Declaration: Artificial Intelligence (AI) tools were used exclusively for language enhancement purposes, specifically to improve the clarity and fluency of English in the manuscript. No AI tools were employed for data analysis, interpretation, or generation of research content.

Abstract: Trust has always been a fundamental element of organisational and social structures, enabling cooperation in situations where uncertainty or vulnerability cannot be fully eliminated. As societies and infrastructures have become increasingly interconnected, the foundations of trust have shifted from interpersonal relationships toward complex institutional and technological arrangements. This evolution has reached a new turning point: digital infrastructures, autonomous systems, and data-driven decision-making processes increasingly mediate interactions that once relied on human reasoning. Artificial intelligence (AI) is reshaping expectations of reliability, transparency, and accountability, prompting a reassessment of what it means to trust in environments where human and machine actions are intertwined. In this context, the notion of trustworthy AI has emerged as a key prerequisite for the responsible integration of AI systems into social and technical ecosystems. Core principles such as robustness, explainability, fairness, and security are widely regarded as essential for fostering a balanced relationship of trust. These requirements become especially significant in domains where AI supports or controls essential services. This is particularly true for critical infrastructures - energy grids, transportation systems, healthcare services, and communication networks-, where AI-driven decisions may trigger cascading effects that extend far beyond individual users. Ensuring trustworthy behaviour in such settings requires not only technical reliability but also governance structures that provide oversight, recourse, and continuous assurance. Despite broad agreement on the importance of trustworthiness, a substantial trust gap persists. Users often struggle to understand how AI systems reach their decisions, leading to scepticism or disengagement. Conversely, operators may place unwarranted confidence in automated outputs, especially in high-pressure or resource-constrained environments. Organisations face challenges translating abstract principles into operational practices, and regulatory frameworks remain inconsistent across sectors and jurisdictions. These tensions illustrate that trust cannot be created through technical means alone; it must be cultivated through transparent design, institutional accountability, and alignment with societal values.

Keywords: Trust**,** Trustworthiness, Trusted AI, Artificial intelligence

1. Introduction and Motivation

Trust is a foundational mechanism that enables coordinated action under uncertainty. Classical accounts frame trust as a way of reducing complexity in situations where full information or control is not possible (Luhmann, 1979; Gambetta, 1988). In modern societies, this function has increasingly been delegated to large-scale socio-technical systems, such as financial platforms, communication networks, healthcare systems, and energy infrastructures, where trust is no longer placed solely in individuals, but in the reliability and governance of the systems themselves.

This shift has reached a critical point with the rise of Artificial Intelligence (AI) methods. Unlike traditional software systems, AI models are inherently data-driven, probabilistic, and often opaque. Their behavior emerges from statistical patterns rather than explicitly defined rules, making it difficult to fully predict, interpret, or verify their decisions. As a result, AI challenges traditional engineering assumptions that underpin trust, namely determinism, transparency, and verifiability. Instead, trust in AI-enabled environments must be established under conditions of uncertainty, approximation, and evolving system behavior.

At the same time, AI is no longer confined to low-stakes applications. It is increasingly embedded in decision-making processes that affect safety-critical and societally significant outcomes. In domains such as healthcare, finance, transportation, and public administration, AI systems influence or automate decisions that were historically made by human experts. Empirical research in human–automation interaction shows that users struggle to calibrate their trust in such systems, often exhibiting over-reliance (automation bias) or under-reliance (algorithm aversion), depending on how system behavior is perceived and communicated (Parasuraman & Riley, 1997; Dietvorst, Simmons and Massey, 2015). This miscalibration highlights a fundamental problem: trust in AI is not simply a function of system performance, but depends on how technical capabilities align with human expectations, organizational practices, and institutional safeguards.

In response, the concept of trustworthy AI has emerged as a central organizing principle in both research and policy. Influential frameworks developed by bodies such as the European Commission, the Organization for Economic Co-operation and Development (OECD), and the National Institute of Standards and Technology (NIST) converge on a set of core requirements, including robustness, reliability, transparency, fairness, accountability, and human oversight. These principles reflect a broad consensus that trustworthiness must be engineered and governed across the lifecycle of AI systems, rather than assumed as an emergent property.

However, despite this convergence at the level of principles, a substantial gap remains between normative guidance and operational practice. Much of the existing work addresses individual dimensions of trustworthiness—such as explainability, fairness, or robustness—in isolation. Yet real-world systems require these properties to coexist and interact under constraints, often involving trade-offs. For example, improving model interpretability may reduce predictive performance, while increasing robustness to adversarial inputs can raise system complexity and reduce transparency. Moreover, improvements in technical metrics do not necessarily translate into appropriate user trust when system behavior remains difficult to interpret or contextualize.

These challenges become significantly more pronounced in the context of critical infrastructures. Systems such as energy grids, transportation networks, and healthcare services operate under strict requirements for reliability, safety, and continuity. They are also deeply interconnected, meaning that failures can propagate across subsystems and produce cascading effects. When AI is introduced into these environments, it does not merely augment existing processes; it becomes part of a tightly coupled cyber-physical system in which errors, uncertainties, or adversarial manipulations may have systemic consequences. Prior work on cyber-physical security demonstrates that such systems are particularly vulnerable to complex interactions between digital and physical components (Cardenas, Amin and Sastry, 2008; Rajkumar et al., 2010).

At the same time, advances in machine learning have revealed fundamental limitations in current approaches to reliability and robustness. Research on adversarial machine learning shows that even highly accurate models can fail under small, carefully crafted perturbations (Goodfellow, Shlens and Szegedy, 2015; Papernot et al., 2016). Studies on distributional shift and uncertainty estimation similarly demonstrate that models often behave unpredictably when exposed to conditions that differ from their training data (Hendrycks & Gimpel 2017; Gal & Ghahramani 2016). These findings challenge the assumption that strong benchmark performance is sufficient for trustworthy deployment in operational environments.

Taken together, these developments point to a fundamental tension. On the one hand, AI offers unprecedented capabilities for optimization, prediction, and automation in complex systems. On the other hand, the very properties that enable these capabilities also introduce new forms of uncertainty and risk. This tension is particularly acute in critical infrastructures, where the consequences of failure are systemic rather than local.

The motivation for this work is to address the fragmentation that currently characterizes research on trustworthy AI. Rather than treating trustworthiness as a collection of independent technical properties, this paper adopts an integrated socio-technical perspective that situates trust within organizational practices and institutional governance. Focusing on critical infrastructures as a high-stakes domain, the paper examines trust not as a static property achieved at design time, but as a dynamic relationship that must be continuously established, calibrated, and sustained over the lifecycle of AI-mediated systems (Lipps et al., 2024).

2. Background and State of the Art: Trust and Trustworthy AI

The study of trust naturally appears in multiple disciplines, including sociology, philosophy, economics, and, more recently, computer science. Early conceptualizations characterized trust as a mechanism for reducing social complexity (Luhmann, 1979) or as a rational expectation under uncertainty (Gambetta, 1988). In these accounts, trust is not blind confidence but a calibrated judgement that balances risk, evidence, and prior experience. This foundational view remains relevant in AI-mediated contexts, where uncertainty arises from data dependence, model approximation, and environmental variability.

Before the emergence of modern AI, research on trust in automation established principles that continue to inform current work. Studies in human factors showed that trust in automated systems is dynamic and context-dependent, evolving with system performance and user experience (Lee & See 2004). Inappropriate trust manifests in two forms: misuse (over-reliance) and disuse (underutilization), a framing that closely aligns with contemporary discussions of automation bias (Parasuraman & Riley 1997) and algorithm aversion (Dietvorst, Simmons and Massey, 2015).

Empirical work further demonstrated that users calibrate trust based not only on perceived reliability, but also on transparency and feedback. Even minor observable errors in algorithmic systems can lead to disproportionate loss of trust despite superior overall performance (Dietvorst, Simmons and Massey, 2015). These findings underscore that trust is shaped by how system behavior is communicated and interpreted, not solely by objective accuracy.

A central theme in recent work is the explicit distinction between trust and trustworthiness: Trust denotes a subjective human attitude or a *willingness* to accept vulnerability in light of uncertainty, whereas trustworthiness refers to properties of a system that can, in principle, be specified, evaluated, and justified independently of individual belief states. Recent work in communications engineering has emphasized this distinction, arguing that technical systems cannot be trusted in a moral or intentional sense but can only be made trustworthy by design through measurable system characteristics and governance mechanisms (Fettweis et al., 2025). Clarifying this distinction is crucial, as conflating trust with trustworthiness risks treating technical compliance or high performance as sufficient for the establishment of appropriate human trust.

2.1 From Trustworthy Automation to Trustworthy AI

The transition from traditional automation to AI introduces new challenges. Unlike rule-based systems, machine-learning models often lack explicit, human-interpretable logic, leading to their characterization as “black boxes” (Lipton 2018). This opacity complicates verification, validation, and accountability, particularly in high-stakes domains. In response, the field of explainable AI (XAI) has emerged, proposing techniques such as Local Interpretable Model-agnostic Explanations (LIME) (Ribeiro, Singh and Guestrin, 2016) and Shapley Additive explanations (SHAP) (Lundberg & Lee 2017) to provide local or global explanations of model behavior. While such methods can improve interpretability, their ability to foster genuine understanding and appropriately calibrated trust remains contested. Explanations may increase user confidence without improving decision quality, thereby reinforcing risks of over-trust. Parallel efforts address robustness and reliability, particularly regarding adversarial manipulation and distributional shift. Research has shown that highly accurate models can fail under small perturbations (Goodfellow et al. 2015) or when deployed in environments that differ from training conditions (Hendrycks & Gimpel 2017). Together, these findings challenge the assumption that technical performance alone is sufficient for trustworthy deployment.

2.2 Fairness, Accountability and Ethical AI

Another core dimension of trustworthy AI concerns fairness and bias. Machine-learning systems can inherit and amplify biases present in training data, leading to discriminatory outcomes (O’Neil, 2016; Buolamwini & Gebru, 2018). This has motivated the development of fairness-aware learning approaches (Barocas, Hardt & Narayanan, 2019) and algorithmic auditing frameworks. Accountability extends the focus beyond technical correctness to include traceability, auditability, and responsibility assignment. Documentation mechanisms such as model cards (Mitchell et al., 2019) and datasheets for datasets (Gebru et al., 2018) support transparency and governance, but do not by themselves resolve questions of institutional oversight or liability.

2.3 Formalizing Trustworthy AI

Efforts to formalize trustworthy AI have converged around common principles. Frameworks proposed by the European Commission (2019), the OECD (2019), and the NIST AI Risk Management Framework (2023) emphasize robustness, transparency, fairness, accountability, and human oversight across the AI lifecycle. Despite broad alignment, these frameworks remain largely high-level and normative. Translating them into operational practices for complex, real-world systems remains challenging, particularly given trade-offs between transparency, privacy, robustness, and performance.

2.4 Limitations of the Current State of the Art

The current literature reveals several persistent limitations. First, research often addresses individual dimensions of trustworthiness -such as explainability, robustness, or fairness-, in isolation, neglecting their interaction within integrated systems. Second, improvements in technical metrics do not reliably translate into appropriately calibrated human trust, reinforcing the gap between trustworthiness and trust. Third, many approaches implicitly assume static deployment contexts, whereas real-world systems -especially in critical infrastructures-, are dynamic, adaptive, and exposed to evolving risks. Finally, trust is frequently treated as a property of the AI system itself rather than as an emergent phenomenon arising from interactions between technology, users, organizations, and institutions. This system-centric perspective limits the ability of existing

approaches to explain how trust is established, calibrated, and sustained in operational environments, thereby motivating the need for an explicitly socio-technical perspective.

2.5 The Trust Gap in AI -Mediated Systems

Despite growing convergence around principles of trustworthy AI, a persistent gap remains between AI systems that satisfy formal trustworthiness criteria and the way they are actually trusted, relied upon, or resisted in practice. This trust gap refers to a misalignment between objective system properties and the subjective or institutional trust relationships that govern real-world use. Similar gaps have long been discussed in the literature on trust and automation, where improved system performance does not necessarily lead to appropriate reliance (Lee & See, 2004; Hancock et al., 2011).

This misalignment emerges from the interaction of system properties, human judgement, and organizational context, and is conceptually summarized in Fig. 1.

2.6 Conceptualizing the Trust gap

A central source of this gap lies in the distinction between trust and trustworthiness. Trust is commonly defined as a willingness to accept vulnerability under conditions of uncertainty, based on expectations about the behavior of others (Luhmann, 1979; Mayer, Davis & Schoorman, 1995). Trustworthiness, by contrast, refers to properties of the trusted entity—such as ability, integrity, robustness, or reliability—that can be evaluated independently of the trustor's subjective belief. Recent work in both social sciences and engineering highlights the importance of maintaining this distinction, particularly in socio-technical systems where trust is often misattributed to technical artefacts (Bauer, 2021; Fettweis et al., 2025).

The trust gap emerges when improvements in trustworthiness—such as higher accuracy, explainability, or robustness—do not translate into appropriately calibrated trust. Conversely, trust may be placed in systems whose trustworthiness is insufficient. This misalignment reflects not a simple failure of technical performance, but a broader disconnect between system behavior, human expectations, organizational routines, and institutional safeguards.

2.7 Opacity, Uncertainty, and Miscalibrated Trust

The epistemic opacity of AI systems is a key contributor to the trust gap. Machine-learning models, particularly deep learning systems, operate on high-dimensional statistical representations that resist full interpretation or prediction. This opacity is structural rather than accidental, arising from the mathematical and computational foundations of machine learning (Burrell 2016). While explainable AI techniques attempt to mitigate this issue, they typically provide local or approximate explanations rather than comprehensive understanding (Lipton, 2018; Doshi-Velez & Kim, 2017).

Empirical studies suggest that such explanations can increase user confidence without necessarily improving decision quality or understanding of uncertainty (Binns et al., 2018; Ehsan et al. 2021). This creates a risk of illusory transparency, in which systems appear more trustworthy than they actually are. As a result, users often struggle to assess when a system's outputs are reliable, when uncertainty is high, or when human judgement should prevail.

These epistemic limitations translate directly into miscalibrated trust. Research in human–automation interaction shows that users frequently exhibit automation bias, deferring too readily to system recommendations, as well as algorithm aversion, rejecting AI support following salient failures (Parasuraman & Riley, 1997; Dietvorst, Simmons & Massey, 2015). Crucially, over-trust and under-trust are not opposing phenomena but manifestations of the same calibration problem: the absence of meaningful cues for assessing system competence across contexts (Lee & See, 2004).

2.8 Organizational and Institutional Mediation of Trust

Trust in AI-mediated systems is rarely formed at the level of individual cognition alone. AI systems are embedded in organizational settings that strongly shape how trust is constructed and enacted. Standard operating procedures, interface designs, training regimes, time pressure, and incentive structures influence whether and how AI outputs are used (Möllering, 2006). In many cases, reliance on AI reflects organizational compliance rather than genuine belief in system reliability.

This organizational mediation of trust also affects accountability. Responsibility for AI-mediated outcomes is typically distributed across developers, system integrators, operators, and regulators. Such fragmentation

complicates responsibility attribution and creates moral distance between decisions and consequences (Nissenbaum, 1996). When it is unclear who is accountable for errors or harms, trust becomes fragile—even when systems behave as designed.

While "human-in-the-loop" approaches are often proposed as safeguards, empirical and conceptual work suggests that nominal human oversight does not automatically resolve accountability concerns. When intervention authority is limited or poorly supported, human oversight may serve primarily as a symbolic reassurance rather than a substantive control mechanism (Kroll et al., 2017; Pasquale, 2015).

2.9 Trust as a Dynamic and Context-Sensitive Process

A further dimension of the trust gap is its temporal character. Trust in AI-mediated systems evolves over time as systems are updated, retrained, or deployed in new environments, and as organizational practices and regulatory expectations change. Static assessments of trustworthiness at design or deployment time cannot account for distributional shift, emerging vulnerabilities, or changes in operational context (Hoff & Bashir, 2015; Amodei et al., 2016).

Empirical studies show that trust is highly sensitive to experience and feedback, and can erode even in the absence of discrete failures if system behavior becomes less predictable or less intelligible (Hancock et al., 2011). This highlights the inadequacy of one-time certification or compliance-based approaches to trustworthiness. Trust must instead be continuously established, monitored, and recalibrated throughout the system lifecycle.

Taken together, these insights show that the trust gap in AI-mediated systems arises from the interaction of technical opacity, human cognitive limitations, organizational mediation, and institutional accountability structures. Closing this gap requires treating trust not as a static property engineered into systems, but as a socio-technical relationship embedded in context and sustained over time (Lipps, Scharwatz and Collier, 2026).

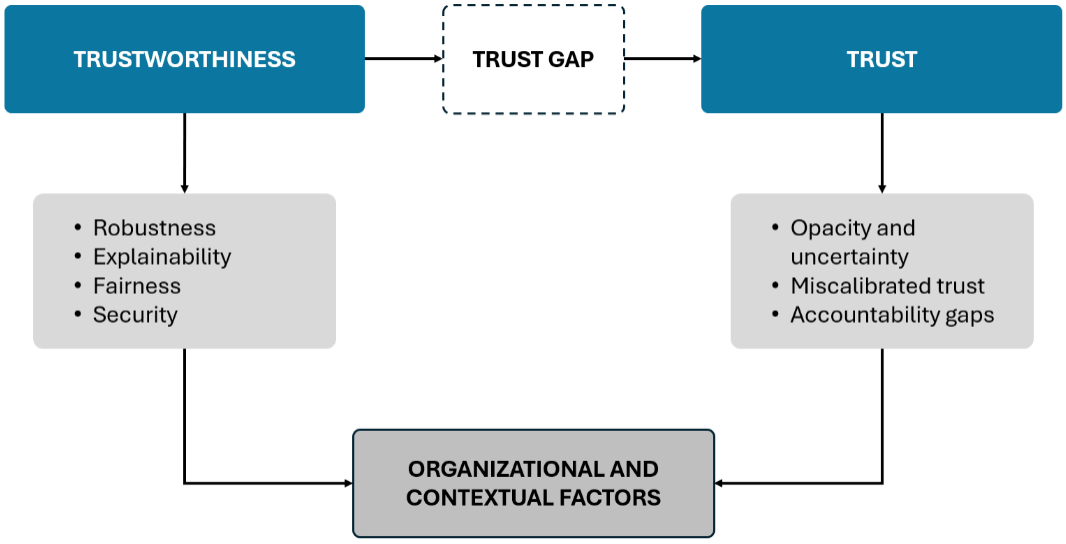

Figure 1: Conceptual illustration of the trust gap in AI-mediated systems

Objective trustworthiness properties of AI systems do not translate directly into established trust. The gap between trustworthiness and trust is mediated by organizational, contextual, and institutional factors that shape how AI systems are understood, relied upon, and governed.

3. Trustworthy AI in Critical Infrastructures

Trustworthy AI is particularly important in critical infrastructure environments because these systems provide services on which society depends, including electricity, water, transportation, healthcare, finance, telecommunications, and public safety. In such contexts, AI failure is not merely a technical inconvenience. It may affect physical safety, service continuity, public confidence, economic stability, and national security. This makes critical infrastructure a distinct setting for trustworthy AI: the central concern is not only whether an AI system performs well under nominal conditions, but whether it can be relied upon under operational stress, uncertainty, cyberattack, and changing environmental conditions.

Critical infrastructures are increasingly cyber-physical systems in which digital decisions produce physical consequences. AI may be used to detect anomalies in power grids, optimize traffic flows, support clinical triage, identify cyber intrusions, allocate scarce resources, or predict equipment failure. These applications can enhance efficiency and resilience, but they also introduce new forms of dependency. When AI becomes embedded in operational decision-making, errors can propagate across interconnected subsystems. A faulty prediction in one component may influence scheduling, control actions, maintenance planning, emergency response, or downstream infrastructure dependencies. For this reason, trustworthy AI in critical infrastructure must be understood as a system-level property, not a model-level attribute.

The NIST AI Risk Management Framework identifies characteristics of trustworthy AI such as validity and reliability, safety, security and resilience, accountability and transparency, explainability and interpretability, privacy enhancement, and fairness with harmful bias managed (NIST, 2023). These characteristics are especially relevant in critical infrastructure, where the cost of misplaced trust is high. A model that is accurate under normal operating conditions may still be untrustworthy if it fails under distribution shift, cannot detect uncertainty, lacks auditability, or cannot be overridden by human operators. NIST's recent work on a dedicated profile for trustworthy AI in critical infrastructure reinforces the need for sector-specific guidance spanning information technology, operational technology, and industrial control systems (NIST, 2026).

A key challenge is that critical infrastructure environments are often safety-critical, time-sensitive, and adversarial. In ordinary commercial settings, AI errors may result in inconvenience, reputational damage, or financial loss. In contrast, failures in critical infrastructure can compromise essential services or endanger human life. For example, AI-driven optimization in an energy grid must not only be efficient but also stable, secure, and robust against sensor faults, data poisoning, adversarial manipulation, and unexpected demand patterns. Similarly, AI used in healthcare or emergency response must support timely decision-making without obscuring responsibility or weakening professional judgement.

Cybersecurity is central in this context. Infrastructure operators increasingly deploy AI for threat detection, anomaly detection, and automated response. However, AI systems themselves become attack surfaces. ENISA distinguishes multiple dimensions of the AI–cybersecurity relationship: using AI to support cybersecurity, securing AI systems themselves, and addressing malicious uses of AI (ENISA, 2020; ENISA, 2025). This distinction is important because it avoids a one-sided view of AI as merely a defensive tool. In critical infrastructures, trustworthy AI must therefore include protection against adversarial examples, data poisoning, model theft, prompt injection, unsafe automation, and compromised supply chains.

Governance and accountability are equally important. The United States Department of Homeland Security emphasizes that responsibility for trustworthy AI in critical infrastructure is distributed across AI developers, cloud and compute providers, infrastructure owners and operators, regulators, and public authorities (US DHS 2024). No single actor can guarantee trustworthiness in isolation. Developers may design robust models, but operators must deploy them safely; infrastructure providers must secure platforms; regulators must define obligations; and affected stakeholders must have access to transparency and recourse mechanisms.

The European Union's AI Act similarly classifies certain AI systems used as safety components in the operation and management of critical infrastructure as high-risk systems. This reflects a broader regulatory judgement: where AI affects essential services, heightened requirements apply for risk management, data governance, technical documentation, human oversight, accuracy, robustness, and cybersecurity (European Union, 2024). The significance of this classification is not merely legal. It confirms that trustworthiness must be demonstrated through evidence, documentation, and lifecycle controls, rather than asserted through general ethical claims.

For this reason, trustworthy AI in critical infrastructure requires continuous assurance. Pre-deployment testing is necessary but insufficient. Models must be monitored after deployment for performance degradation, concept drift, abnormal inputs, and emerging threats. Operators require explanations that are actionable, not merely visual or statistical. They must know when to rely on the system, when to challenge it, and when to revert to fallback procedures or human control.

A growing body of applied research has begun to address these challenges, particularly in cyber-physical infrastructure systems. For example, *Munir, Shetty, and Rawat* (2023) propose a trustworthy AI framework for smart-grid cyber-attack detection that integrates reliability, explainability, transparency, fairness, and accountability into a unified pipeline. Their approach combines machine-learning-based detection with SHAP-based explanations and dynamic risk quantification, demonstrating that trustworthiness can be operationalized as measurable system properties within a real infrastructure context.

Complementing this, conceptual work on governance and accountability highlights that trustworthy AI in infrastructure systems requires clear responsibility allocation and regulatory alignment. Recent analyses of AI-enabled energy systems (Volkova et al., 2024) argue that traceability of decisions and accountability structures must be considered integral to trustworthiness, rather than external constraints. This reinforces the view that trust in critical infrastructures is inherently socio-technical.

In summary, critical infrastructure intensifies the trustworthy AI problem because reliability, security, accountability, and resilience cannot be separated. Trust cannot be reduced to user confidence or predictive accuracy. It must be grounded in demonstrable technical performance, robust cyber-physical safeguards, institutional accountability, and continuous operational assurance. These characteristics make critical infrastructure a key domain for translating trustworthy AI from abstract principles into practical, auditable, and enforceable socio-technical systems.

4. Conclusion and Future Work

Artificial Intelligence systems are increasingly integrated into societal infrastructures and organizational decision-making processes, often in contexts where reliability, safety, and accountability are critical. In response, the notion of trustworthy AI has gained prominence in research, policy, and regulation, resulting in a broad alignment around technical and ethical principles such as robustness, transparency, fairness, and human oversight. Yet, despite this convergence, trust in AI-mediated systems remains fragile, contested, and frequently miscalibrated in practice. This persistent tension indicates that technical trustworthiness alone does not resolve the deeper problem of how trust is established and sustained when human and machine actions are tightly intertwined.

Therefore, this work addresses this gap by examining trust in AI-mediated systems through a socio-technical lens. Drawing on theories of trust, empirical findings from human–automation interaction, and contemporary AI governance frameworks, the analysis demonstrate that trust and trustworthiness are distinct but interdependent concepts. Trustworthiness refers to objective system properties that can be designed, evaluated, and governed, whereas trust describes a willingness to accept vulnerability under uncertainty. The central contribution of this work lies in identifying the trust gap that emerges when these concepts are conflated - when technically trustworthy systems fail to elicit appropriate trust, or when trust is placed despite unresolved limitations.

By analyzing opacity, uncertainty, miscalibrated reliance, organizational mediation, and accountability fragmentation, the work shows that the trust gap is not a marginal or transient phenomenon. Rather, it arises from the interaction of technical system behavior, human judgement, organizational routines, and institutional arrangements. This diagnosis challenges system-centric approaches that treat trust as a property that can be engineered or certified at design time, and instead highlights trust as a dynamic relationship embedded in context.

The analysis further demonstrated that these issues become especially acute in critical infrastructures. In such environments, AI systems operate within tightly coupled cyber-physical systems, where uncertainty, adversarial conditions, and cascading effects are inherent. Here, trust failures have systemic consequences, and ensuring trustworthy behavior requires continuous assurance, clear responsibility allocation, and robust governance across organizational and sectoral boundaries. The discussion of regulatory and institutional perspectives illustrates that trustworthiness must be enacted and maintained over the system lifecycle, not merely asserted through abstract principles.

Several avenues for future research follow from this work: First, empirical studies are needed to investigate how trust in AI-mediated systems evolves over time in real-world organizational contexts, particularly under changing operational conditions. Second, domain-specific analyses of trustworthiness in different critical infrastructure sectors could help translate socio-technical insights into actionable practices. Third, further work should explore governance, auditing, and assurance mechanisms that explicitly address the relational and institutional dimensions of trust identified in this paper.

In conclusion, advancing trustworthy AI requires moving beyond a purely technical understanding of trustworthiness toward an integrated socio-technical perspective on trust. By reframing trust as a dynamic, context-sensitive, and institutionally mediated relationship, this paper provides a conceptual foundation for future efforts to build not only technically sound AI systems, but also resilient and legitimate trust in their deployment.

Cognitive Deception: Cognitive Hacking Phenomenon and Cognitive Security

Mikko Luomala and Jyri Naarmala
University of Vaasa, Finland

mikko.luomala@uwasa.fi
jyri.naarmala@uwasa.fi

Abstract: Cybercriminality is an actively discussed topic in in criminology. While technical cybersecurity has evolved, increasing number of different types of technical solutions have been created to defend against cyberattacks. In security and cybersecurity, the weakest link is often considered to be a human. It seems that while malware attacks are increasing in numbers, also social engineering or cognitive hacking has increased. This paper explores the use and definition of a concept of cognitive deception in previous studies. Used dataset for this study was taken from SCOPUS database and qualitative meta-analysis (QMA) was used for analysing the content of the documents. The QMA method was selected for its suitability in content analysis of scientific-, as well as potential grey literature. Evolving technology has created new approaches for manipulating people. The analysis of research data indicates that cognitive hacking relates to definitions of cybercrime, cyberattack, warfare, and hybrid threats. This study contributes to the discussion about cognitive security.

Keywords: Cybercrime, Criminology, Cognitive deception, Cognitive hacking, Cyberattack, QMA, Qualitative meta-analysis

1. Introduction

Within cyber security, cognitive hacking has been studied (Adefabi et al. (2025). The consequences cognitive hacking has for example on human users who are being targeted to give unauthorized access to computer systems has been studied as well (Cybenko et al., 2002). This type of cyberattacks can be called social engineering where human weaknesses are being exploited (Montañez et al., 2020). Social engineering is used to gain access to confidential information (Washo, 2021). Concept of cognitive hacking can be expanded with the aid of artificial intelligence to deceive people. Cognitive hacking is a form of cyberattack, where misinformation is used to manipulate the opinions of the public in different societal aspects. This is done using psychological means to exploit human weaknesses in cognitive function. In this process, cognitive hacking refers to false information to manipulate the target using cyber-social vulnerability in the information systems. It seems, that technological approach and layer-based thinking in security or cybersecurity could greatly benefit from extending those to include controls for cognitive hacking. In this sense, previous studies have their focus on describing "what is occurring" in social interaction and what this manipulative action causes to the technology, i.e. "description of damages". For example, in a Finnish study about cybercrimes that end up in court, cases are categorized as a regular usage of computers, and not technologically that advanced (Luomala, 2025). This indicates that there is an emerging trend taking place, where the preparation of cybercrimes is shifting from purely technological approach towards more socio-technical approach, where cognitive hacking plays an important role. So, how can this evolutionary transformation be explained? This indicates that there exists a research gap, that is waiting to be found.

Layered security architecture has been seen as a methodology to secure assets (Ghasemi & Babaie, 2024). However, when layered security is penetrated with a human element (Jamuna, 2024) or an inside threat that emerges within the organisation (Anti, 2025; Anti & Vartiainen, 2024), this results a violation of the security (or cybersecurity). Even though the Department of Defence has defined layered strategy to suppress and deter threats from as far away as possible and the layers plays a key element in this defence (Lewis, 2006, p. 5). The layered security model is used to secure for example "Supervisory Control and Data Acquisition" (SCADA) systems, where defence is based on different layers (Knapp and Langill, 2015, p. 32-33). The model is also called as the defence in depth (Caballero, 2014; Morrow, 2021; Shinder & Shinder, 2005). However, it seems that the idea of layered security has a fundamental design flaw. A great amount of research has demonstrated that criminal behaviour is quite common (Howitt, 2006, p. 17), and the "threat" exists already within the system, in the very environment where humans live.

Some studies propose that there is a scam for everyone (Whitty, 2020). However, cyberthreats are created by humans (Lewis, 2006, p. 399), although there is a hypothetical possibility that in the near future artificial intelligence (AI) can generate cyberthreats or cybercrimes (Luomala, 2025). This brings up several important questions for scientific investigation. It could be asked, why are humans considered the weakest link in security and cybersecurity? How is cognitive security defined ontologically? What happens when humans are being manipulated, and do they recognise that they are being manipulated? In what mental stage human is vulnerable

to manipulation? How does manipulation take place? How to defend against cognitive hacking, and what can be done to either prevent, detect or mitigate the effects of cognitive hacking? This paper analyses why theoretically systems are never technically 100% secure (Lewis, 2006, p. 431). In order to understand this problem domain, a research problem is presented for this study: (*RQ) What is the role of cognitive security in the layered security model?*

2. Research Design

For creating a pre-theory for the research question, a qualitative meta-analysis (QMA) is used. QMA is known under three different names, and these are qualitative meta-synthesis (Berente et al., 2019; Habersang et al., 2019; Küberling-Jost, 2021), meta-synthesis (Hoon, 2013; Omanović & Langley, 2023) or qualitative meta-study (Lee et al., 2015; Tamminen & Holt, 2010). In 2024, Ignacio and Schwerer stated that the QMA can be used to examine existing knowledge for searching for new insights. Mengist et al. (2020) suggest that QMA can be used to make interpretations from literature review. According to Noah (2017), the QMA allows usage of secondary data (p. 203) and statistical analysis (p. 196-197). Hagan (2018) describes that researcher can collect field notes (p. 166) and those data can be used in the QMA, because the QMA allows usage different types of data (Noah, 2017). The QMA methodology is not about making simple summarising or cataloguing or review of already published research (Noah, 2017, p. 197). Purpose is to create a new knowledge from existing data (Noah, 2017, p. 197). The QMA methodology is about using original text to discover themes and identifying terms, and from the text interpretations and reflections are made (Noah, 2017, p. 202). “Part of the function of meta-analysis is to correct for differences between studies that are the result of bias, and to highlight differences that are unexplainable by the theory or framework being used” (Weed, 2005, p. 9). Same principle can be applied in qualitative meta-analysis (QMA) (Weed, 2005, p. 9). However, the quality of the QMA relies on researchers’ ability to reflect, make an interpretation from research data and to make conclusions and present results (Noah, 2017, p. 203). The QMA is considered a rigorous research method (Levitt, 2018; Timulak, 2009). The QMA is an inductive research method, and it was chosen for this inductive study. The QMA is used to make a qualitative interpretation from the literature review (Noah, 2017). The interpretation will then be the pre-theory, which is the answer to the research question. This study presents the role cognitive security has in the layered security model and what kind of pre-theory can describe it. In each section the use of methodology is explained in detail.

3. Literature Review with PRISMA Framework

The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) literature review quality system (Page et al., 2021) was used to answer the research question. The data collection, data screening and data processing is described according to the PRISMA framework (Page et al., 2021). Used search parameter for the SCOPUS database was “TITLE-ABS-KEY ("cognitive hacking")”. The search provided 25 documents in 8.12.2025. Documents were 21 full-text articles, 3 abstracts and 1 review version of an article. Nineteen documents (n=19) were included in the research. Figure 1 illustrates the detailed process.

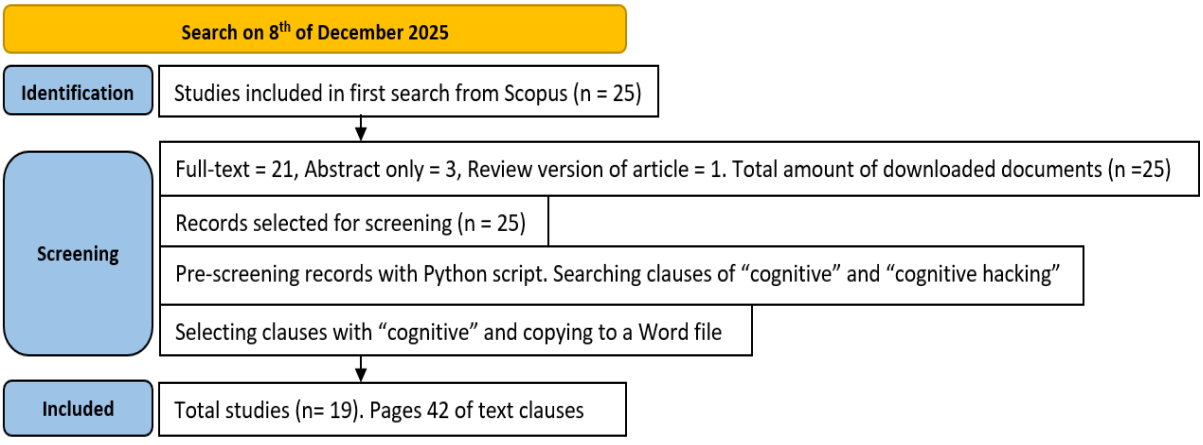

Figure 1: The PRISMA framework for collecting and processing the literature

For converting PDF files to text files, a Python code was created. The python code was run on Windows environment, and a folder was selected where the PDF files were located. The python saved the converted PDF files to the output folder. Another Python code was used for data mining and to collect clauses from the text files. The python code has a language model to detect words from clauses, and it was used to analyse all text

files in the output folder. If the lines of text file contained a word that matched search criterion, it was selected and stored into the output file. The output file had arrays, where filename was located and the collected clauses for each filename.

Sentences with words “cognitive” or “cognitive hacking” were recognized from the text files using a language model (Spacy with "en_core_web_sm"). Recognized clauses were then collected into an Excel file, and finally the output file was transferred to a Word file that made NVivo data coding possible. While analysing the data, it soon became clear, that the clauses of “cognitive” can provide a much richer view for the study, than just selecting clauses which have only “cognitive hacking” words. From there, iteration of the data was repeated. Research process continued by reading the clauses from the Word file. Depraetere et al. (2021) suggest that when critical interpretation synthesis (CIS) is used and iteration process is conducted, themes will emerge from the research data. The CIS methodology created main themes, which were: (i) Theme: attacking the mind; (ii) Theme: definition of cybercrime, cyberattack, hybrid threat, and; (iii) Theme: protecting the mind from cognitive hacking

4. Qualitative Meta-analysis Interpretation for the Proposed Pre-theory of Cognitive Hacking Theory

The layered security model can be defined in several different ways. The layered security is about creating architecture to secure assets with equipment on each layer (Ghasemi & Babaie, 2024). The layered security model includes usage of firewall, intrusion prevention systems and physical security solutions (Knapp and Langill, 2015, p. 32-33). The Department of Defence has defined layered strategy to suppress and deter threats from as far away possible and the layers plays a key element in this defence (Lewis, 2006, p. 5). The layered security model is used to secure for example SCADA (Supervisory Control And Data Acquisition) systems, where defence is based on different layers (Knapp and Langill, 2015, p. 32-33). The model is also called as the defence in depth (Caballero, 2014; Morrow, 2021; Shinder & Shinder, 2005). The purpose of the layered security model is to use technology to create security on each layer. However, when layered security is penetrated with a human element (Jamuna, 2024) or an inside threat which emerges within the organisation (Anti, 2025; Anti & Vartiainen, 2024). The cybersecurity is promised and unwanted event will occur, even it should be technically secure or otherwise it was belief that system is secure.

The three main themes have several sub-themes (Figure 2, Table 1). The contents of sub-themes are explained under the “Themes” headlines. “When presenting the results of the qualitative meta-analysis the researcher should not “boil down” the written word into numeric data, rather he should strive to keep the richness of the original text. Conducting a qualitative meta-analysis requires interpretation and reflectiveness” (Noah, 2017, p. 202). In this section interpretations from the research data are presented as researchers’ own reflection and interpretation, not just cataloguing the text from the literature. The drawn figure 1, the table 1 and three themes are the reflections and interpretations from the research data, which have been created by observing and examining the data in different ways. The proposed pre-theory is presented as synthesis of all interpretations. In this chapter the output of the research is presented, and it is based on the research methodology (Mengist et al., 2020, p. 8). It seems that cognitive hacking can be simplified to be process where human elements are manipulated by other human with the aid of technology as illustrated in Figure 2.

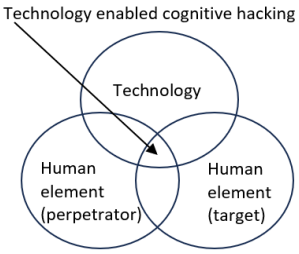

Figure 2: The interpretation of the cognitive hacking relationship to human elements and technology

During the iteration of the clauses, it soon became clear, that the discussion of the security of systems and society is merely related to development of technical solutions than inventing or discovering techniques to secure human element cognition from a form of manipulation. Even though malware and technical attacks are one phenomenon, the connection to the human element, that is manipulated to act the way the manipulator wants, receives minimal attention. Following sections, themes are described and headlines of the themes are interpreted from data.

4.1 Theme: Attacking the Mind

While the theme of attacking the mind was explored, sub-themes indicate that addressing risks from cognitive hacking is relatively scarce. Cognitive hacking targets critical infrastructure, and how to change the behaviour of the targets. In addition, it spreads misinformation and targets multiple people. There are processes that profile their victims based on available information, so the manipulated narrative can be created to cognitively manipulate them. The knowledge of internal processes makes it possible to manipulate people who are working in the organisation and to affect their daily actions.

The victims have vulnerabilities, which make them vulnerable to cognitive hacking. For example, personal traits which lead to the manipulation of beliefs. Cognitive hacking targets also victims who are already multitasking and show decision-making fatigue. One factor for vulnerability is age, but there is a wide range of manipulation for all kinds of people. When the manipulation takes place, a "malicious" action is taken. Increases in self-blame create a vulnerability to cognitive hacking by the adversary, which relates to the individual's internal fundamental assumptions. People will focus on easily accessible and understandable information, and this makes them vulnerable for manipulation if someone provides easily digestible information for them. Individuals' exploitation takes place when their subconscious thought processes are disrupted. People are not fully rational thinkers. Enrici, Ancilli and Lioy (2010) suggests, that:

> *"In particular, people who are high in normative commitment feel obligated to reciprocate gestures and favours maliciously proposed by cognitive attacks by giving up confidential and sensitive information; people who are high in continuance commitment tend to provide information to escalating requests, e.g. as part of an online game just to try to win the game; people who are high in affective commitment tend to provide information because they want to be part of a socially desirable group, or to be accepted."*

People who are trusting, will most likely fall to as victims. Enrici, Ancilli and Lioy (2010) suggests, that: "Moreover, people who are trusting were more likely to fall victim to techniques that try to cultivate trust by a process of establishing a friendly rapport or by reference to likable famous individuals, while others are more responsive to authority figures, and higher degrees of obedience to authority were an important factor in whether people responded to these types of cognitive attacks."

4.2 Theme: Definition of Cybercrime, Cyberattack, Hybrid Threat

The cognitive hacking overlaps with such definitions as cybercrime, cyberattack, information warfare, emotional warfare, hybrid warfare and hybrid threat. This due to the fact, that practitioners who deal with these "issues" classify actions of cognitive hacking in their own professional domain. After all, it is a human action that uses technology for manipulating another person to do something unwanted with technology. Table 1 illustrates how cognitive hacking has a parallel connection to other definitions.

Table 1: Parallel connections of definitions of cognitive hacking.

Cognitive hacking			
Military aspect	**Hybrid threat aspect**	**Cybercriminology aspect**	
Cognitive warfare (Bârgăoanu & Pană, 2024), (Danyk & Briggs, 2023)	Hybrid War/ hybrid warfare (Briggs et al., 2021)	False news (Java et al., 2019)	Social engineering (Java et al., 2019)
Emotive warfare (Briggs et al., 2021)	Hybrid threat (Bârgăoanu & Pană, 2024)	Insider threat (Roy & Chen, 2024)	Online manipulation (Susser et al., 2018)
Cyber warfare techniques (Briggs et al., 2021)	Political influence (Briggs et al., 2021), (Farral, 2017)	Email attacks (Guadagno & Cialdini, 2007)	Abnormal returns of the stock (Liu et al., 2021)
Weaponising the online manipulation (Susser et al., 2018)		Security attacks (Enrici et al., 2010)	Cyber attacks (Liu et al., 2021)
		Semantic attacks (Java et al., 2019)	Phishing websites / Fake online offers (Java et al., 2019)

Cognitive hacking can be used in making false news, manipulating websites for influencing wider audiences, as well as in cognitive manipulation in warfare. It can be used in email attacks, where content is used to persuade or manipulate the receiver and it can also be used to exert political influence or manipulation. Cognitive hacking

can be used in different fields, for example in the finance sector. As a summary, cognitive hacking can be seen as a weaponised method for manipulation.

Table 1 shows, that the definition of cognitive hacking is used to describe the manipulation of human elements with technology in different domains. Each domain has its own classification and scale how they technically and socially construct the meaning of the definition. From the analyses, a few theories were linked to cognitive hacking in the studies. The cognitive hacking is linked to theories of mirage theory (Rrushi, 2011), signal detection theory (Huang et al., 2020; Jiang et al., 2004; Stanislaw & Todorov, 1999), utility-theoretic (Marcum, 1947; Rrushi, 2011; Stanislaw & Todorov, 1999) and the theory of cognitive warfare (Bârgăoanu & Pană, 2024).

4.3 Theme: Protecting the Mind from Cognitive Hacking

An interesting statement in the analysed data suggested that if the technology is the weak point, why not investigate the weakest link in the supply chain, which is an extended cognition i.e. the relation between human and its cognitive artefacts. In this case, the issue lies between the relation of humans and their cognitive artefacts. The decision-making judgments are based on early perception and early cognitive processing instead of later, more systematic consideration of the information. It seems that research focuses more on building secure systems against technical threats but neglects cognitive hacking risks, even though the use of cognitive hacking techniques seems to be emerging. Machine learning technology might be capable of detecting overt threats from social cognitive hacking within content.

Countermeasures for cognitive hacking can be seen as a thought process to detect misinformation before it affects the decision and action of the user. It also includes technical solutions, that ensures information sources where information is validated and does not get manipulated. An example of this could be a situation, where website defacements are blocked by preventing unauthorised access for content manipulation. Other working countermeasures are lowering stress and cognitive overload in the organisation. The personal trait of high normative, continuance or affective commitment, as obedient to authority and wanting to trust, was found to contribute to successful cognitive attacks. In other words, this can be referred as naïve loyalty.

Combating cognitive hacking can be done by preventing unauthorised access to knowledge assets, for countering counter defacements and spoofing. In addition, detecting misinformation at an early stage can prevent it from influencing the behaviour of users. Cybenko et. al. (2002) suggests, that “In single-source cognitive hacking, the user has no independent source of information about the same topic and therefore cannot judge if the information is accurate”. Other means for combating cognitive hacking are giving cognitive training methods that help reduce impulsivity or reducing risk-taking behaviour and increasing procrastination to decrease the success of cognitive hacking. In addition, pointing out manipulative websites, which are engaging in cognitive hacking, can be used.

4.4 Cognitive Hacking: The Interpretation with the QMA

In this study, the QMA is used to create describe pre-theory of cognitive hacking. The pre-theory is proposed, because the literature review did not indicate that such a theory exists. Based on the QMA analysis of the data, a descriptive theory can be proposed. This paper presents a suggested extension to be included in layered security thinking. As such, this is a descriptive theory in a sense Gregor (2006) suggests, keeping the focus on analytically describing the observed phenomenon. In addition, Tomar and Tiwari (2025) mentioned that the Frege–Russell Descriptive Theory defines how describe meaning is constructed. The proposed descriptive pre-theory describes cognitive hacking as a form of activity done by humans. The pre-theory is called “the cognitive hacking theory”. The cognitive hacking means action where other human is manipulating another person. The cognitive hacking can include usage of technology to make manipulation. The pre-theory describes that cognitive hacking is occurring and cognitive hacking can penetrate layered security model, because of flaws existing in human nature. The pre-theory describes that cognitive hacking is used to manipulate another human element with the aid of technology. In a military environment, it is either a hybrid threat or part of hybrid warfare or information influence. In some cases, the technology might be the target itself, but the outcome is to manipulate the human element.

From the perspectives of crime science and criminology, a similar classification can be made. Purpose of the cognitive hacking is to manipulate the human element to gain, for example criminal financial gains. Technology works as a mediating device, or an aid in that environment. From the perspective of security studies and political science, technology is an aid for cognitive hacking to influence people to change their ways. It remains philosophically interesting to question what belief can be classified as truly misinformation or disinformation, because in politics, facts are not necessarily things which debate with each other. The proposal for cognitive

hacking theory includes also the basic discovery, that technology itself does not automatically protect from cognitive manipulation. It is rather a part of evolution where technology gives opportunities to manipulate human element, and the security or cybersecurity that is created inside the technology is to mitigate some cyberattacks, cybercrimes and hybrid threats.

Proposed cognitive hacking theory combines different taxonomies of security and cybersecurity, where classifications for cyber-depended manipulations or cyber enabled manipulations are used, however these are better known as cyber-depended crimes or cyber enabled crimes in criminology (Leukfeldt et al., 2020; Lusthaus et al., 2025; McGuire & Dowling, 2013). This can be derived from Alkaabi's et al. (2010) and Luomala's (2025) discussion of types of crimes. In the proposed theory cognitive hacking theory, the manipulation has a dimension named technology aided action, although the target can be influenced through manipulating human element, which have a parallel connection to Luomala's (2025) classification of type III crimes. The type III crimes mean condition where technology is a target and technology is an aid for criminal action. Technically, it means that cognitive hacking is used to manipulate a person to chance parameters of the technical artefact, which then results an alternative effect on other person to trust provided information (Type I, cyber-dependent crime). Existing technologies can be used directly to manipulate a target person (Type II, cyber-enabled crime). These types of I and II can be related to the same crime or they can be separate. When a Type I crime takes place, and it is targeted to technology, it can create an opportunity to commit a Type II crime against an individual. In addition, Luomala's (2025) extended taxonomy suggests, that cybercrime could be done by artificial intelligence. This way the presented taxonomy could be extended to cover also artificial intelligence mediated cybercrimes, and that would be Type IV crime. Reason for this is the capability of AI to be able to do both, manipulation of technology as well as cognitive manipulation against humans.

Alkaabi et al. (2010) suggests that there are Type I and Type II crimes: Type I considers technical device or software as a target of crime, while Type II considers technical device or software as aid for committing a crime. Luomala (2025) extended the taxonomy by adding Type III crimes where technical device or software is a target and aid for committing a crime (p. 50). The proposed cognitive hacking theory extends previous discoveries, where technical hacking has also elements of social manipulation, which are hidden qualitative aspects of cyberattacks, cybercrimes or hybrid threats. "The CCSTC extension with type III extension will show that cybercrime is sophisticated phenomenon and there many hidden qualitative aspects which should be measured such as have offender used social skills to commit the cybercrimes, and the most cybercrime cases are regular usage of the computer which end up to the Finnish court" (Luomala, 2025, p. 50).

Moreover, the cognitive hacking theory suggests, that the human element has internal vulnerabilities, which the layered security model has failed to address. According to the layered security model, the threat comes from the outside of the protected environment. However, the layered security environment is operated and managed by human elements. Therefore, it poses a risk of an insider threat. The layered security model mitigates the use of the system. It means that the system can be used only in certain ways and certain technical "functions" are either blocked, limited or mitigated. Cognitive hacking can penetrate these technical controls by manipulating the human element. Then the system is being used in ways, where legitimate actions are authorised from the systems perspective. However, the actions cause the "unwanted" phenomenon or impact.

5. Discussion

Cognitive hacking opens a discussion about the layered security model. When security and cybersecurity become technically so advanced, that the capabilities of the cyber offender do not necessarily find a way to bypass them, it becomes an obsolete path for cyber offender. In this case the goal shifts into finding a person, who can do everything the cyber offender needs to do. General approach has been merely on treating the symptoms, and not the cause or the discovery of where the "intention" to commit cognitive hacking merges. In this context, it is worth noticing that AI can be expanded to aid in deceiving people (Park et al., 2024). As such, the rules of the game are constantly changing.

From an engineering point of view, it is a worthy discussion to define what is an effective technical solution to "protect" the asset. However, it seems that there always exists a method to get a "malicious" act done by a person who has access and control over the system. From a legal perspective, it can be argued that the system allows only certain actions, and there is a criminal code for actions that are illegal — and this is expected to prevent "illegal" actions. However, people find ways to rationalise their actions, for example when they choose not to follow information security policy (Siponen & Vance, 2010).

There are criminological theories explaining crime (Onwuadiamu, 2025; Renzetti, 2008). Theories are such as rational choice theory, pressure theory, social learning theory, routine theory, etc. (Kivivuori et al., 2018). These theories explain from individual perspective reasons for the crime, but because cybercrime is complex phenomena involving multiple different human actors doing different "cybercrimes", and these are defined differently by different practitioners in different disciplines such as military science, security studies or criminology. A tricky question is to define a comprehensive concept for understanding "what works" against cybercriminality, because it seems to be able to an act of human behaviour. Moreover, the cognitive hacking needs more research on how artificial intelligence (AI) assisted cognitive manipulation is done. The word "artificial intelligence" was seldom mentioned in the documents, and it was mentioned as a method to detect online hoax information (Java et al., 2019) or as a part of hybrid threat (Stevens et al., 2021). In cyber domain there is a need for a theory, that explains the phenomenon of cognitive hacking what military, police or private security encounters, even if their perspective on the phenomena might be different.

The cognitive hacking relates to different types of security threats such as cybercrime, hybrid threats and cyberattacks. Cognitive hacking makes it possible to penetrate layered security model environments. The focus on security must be also on human elements, i.e. making humans aware, that they can be manipulated or become vulnerable to manipulation. The pre-theory of cognitive hacking theory, which is proposed in this study, shows that technology cannot solve issues, that exist within humanity and the human mind.

Cybercrime prevention, prevention of hybrid threats or responding to information influencing is looking for solutions to deal with this type of cognitive hacking. This qualitative meta-analysis shows, that developing effective security and cybersecurity needs evidence-based knowledge. The focus in security, cybersecurity, crime prevention, military operations and governmental security must shift towards making human element more secure by focusing more on cognitive security. It has been said that every study is as credible as the research data (Kaye & Freedman, 2011). It seems that cognitive hacking is not very widely investigated, so there is no common research tradition on how cognitive hacking should be understood (see table 1).

Different domains within the security field deal with similar human element issues, even though they classify their issue as either a cyberattack, cybercrime, hybrid threat or information warfare. It seems that this issue has been attempted to be resolved by implementing primarily technical solutions to address the weaknesses of the systems. A worthy, but understudied avenue would be to focus on understanding why humans have cognitive vulnerabilities. When does the human element become vulnerable to cognitive hacking? In addition, in contemporary society and time, the studies on what can be done to prevent cognitive hacking in an effective way are to be encouraged. Also, the role of AI should be studied — especially in AI mediated cognitive hacking?

The proposed cognitive hacking theory suggests that the layered security model has a vulnerability in cognitive security, which is not addressed. By using cognitive hacking, the technological layered security model systems can be penetrated, and unwanted actions can take place when the human elements are manipulated. The cognitive hacking phenomenon is not isolated only to cybercrime and financial crimes. It includes actions where people's public opinion can be manipulated in the political domain, or perception of the situation can be influenced through information warfare. Currently, there are no clear methods to address the issue of cognitive hacking, but in future studies, techniques to secure the human element are vital. The concept of cognitive security needs to be re-invented or re-discovered. Also, the role of AI-assisted cognitive manipulation should be studied more.

Ethics Declaration: An ethical declaration was not required for the research.

Artificial Immune System for Proportionality Assessment in Military Operations

Clara Maathuis
Open University of the Netherlands, Heerlen, The Netherlands

clara.maathuis@ou.nl

Abstract: This article presents an Artificial Immune System (AIS) algorithm for conducting the proportionality assessment in military operations that integrates an in-depth evaluation in relation to the detection of disproportionate collateral damage in military operations under two modelling settings, as follows defined. In the first modelling setting, the collateral damage only includes physical harm, and in the second modelling setting, the collateral damage includes both physical and psychological harm. In this context, various algorithms were implemented and compared. By employing a Clonal Selection algorithm, the possible scenario-feature combinations are treated as antigens and evolve a detector repertoire via affinity-based cloning, mutation, and replacement and aspects such as detection rate, false-positive rate, and detector diversity are tracked over generations. By employing Negative Selection and Immune Network paradigms, it can be seen that in Case 2 superior disproportional detection is achieved and through a more in-depth network analysis the core communities that underpin disproportionate judgments are analysed. Hence, the AIS models developed demonstrate that incorporating psychological considerations not only improves detection performance, but also shapes the structural properties of immune repertoires, providing a novel computational perspective on the proportionality assessment execution in military operations.

Keywords: Military operations, Proportionality, Artificial intelligence, Artificial immune system

1. Introduction

motto: *"The machine does not isolate man from the great problems of nature but plunges him more deeply into them." (Norbert Wiener)*

Computational modelling techniques have advanced rapidly over the past two decades, driven by increases in data availability, algorithmic sophistication, and computational power (Carothers et al., 2017; Iqbal et al., 2020). From classical rule-based expert systems to modern deep learning architectures, intelligent models now assure the development and deployment of applications ranging from natural language processing to autonomous control (Sarker, 2022). Simultaneously, hybrid paradigms that integrate mechanistic models (e.g., agent-based simulation, system dynamics) with data-driven methods have emerged, enabling both interpretability and predictive accuracy. These developments have transformed how complex socio-technical systems are understood and managed (Howick, S., & Megiddo, 2024; Mazzetto, 2024).

Concurrently, decision-support systems have proliferated across critical domains such as healthcare, finance, energy, and transportation providing stakeholders with the ability to explore what-if scenarios, quantify risks, and optimize interventions under uncertainty. For instance, reinforcement learning agents optimize resource allocation in logistics networks, while probabilistic graphical models forecast disease outbreaks (Ling, Mondal & Ukkusuri, 2024). At the same time, high-fidelity digital twins mirror real-world operations in real time, supporting adaptive control and human-machine teaming (Folds & McDermott, 2019; Maathuis, 2022). Such computational advances have elevated the rigor and responsiveness of decision-making processes in dynamic environments.

In the military domain, computational models play an equally pivotal role, underpinning tasks such as force deployment planning, logistics optimization, cyber-defence, and battlefield simulation (Marin, 2021). Furthermore, agent-based and wargaming frameworks enable commanders to simulate adversary behaviours and assess course-of-action alternatives while Network-centric analytics fuse intelligence, surveillance, and reconnaissance data to generate coherent operational pictures (James et al., 2017; Layton, 2021).

Specifically, a foundational military decision-making targeting process is the principle of proportionality, which is a fundamental targeting principle that mandates that any attack's expected military advantage must not be outweighed by foreseeable collateral damage to civilians and civilian infrastructure (AP, 1977). This requires quantifying two components: the collateral damage (civilian injury, death, and property destruction) and military advantage, and from there balancing them in real time. This represents both a legal and ethical judgement which needs to ensure that force is applied judiciously and in accordance with the laws of armed conflict (Schmitt & Schauss, 2019; Cohen & Zlotogorski, 2021; Maathuis & Kerkhof, 2023; Goździewicz, 2024). Despite the centrality of proportionality in operational doctrine, existing computational models for military

decision-support rarely address automated proportionality assessment (Cools & Maathuis, 2024). While logistics, targeting, and risk-analysis tools abound, few incorporate the structured, multi-dimensional trade-offs inherent in balancing harm and advantage. Consequently, decision-makers lack decision-support systems that transparently integrate proportionality criteria into real-time planning and engagement workflows.

To tackle this knowledge gap, the present research develops an Artificial Immune System (AIS)–based model for proportionality assessment in military operations. In this context, each possible engagement scenario is defined by civilian injury, death, object damage, and military advantage as an antigen that further evolves a repertoire of detectors through negative-selection and clonal-selection mechanisms to distinguish proportionate from disproportionate cases. To this end, two use-case perspectives are considered: one excluding psychological harm from the collateral damage component and one including it. From here, for evaluation and demonstration purposes, a comprehensive hyperparameter optimization and evaluation process quantifies the AIS's sensitivity, specificity, and structural robustness across both cases.

By embedding proportionality rules within a bio-inspired adaptive framework, this AIS model supports responsible decision-making under uncertainty (Maathuis & Chockalingam, 2022). At the same time, through extensive simulations, sensitivity analyses, and network-based metrics, it is shown how non-physical harm considerations influence detection performance and repertoire connectivity. The resulting decision-support artifact provides military decision-makers with a novel tool for upholding proportionality principles in dynamic operational contexts. Hence, this research makes three primary contributions. First, the formulation of proportionality assessment as an AIS problem with explicit antigen–detector mappings. Second, the development and tuning of negative-selection and clonal-selection protocols to optimize detection of disproportionate scenarios under two collateral-damage cases. And third, the introduction of immune-network analyses to characterize detector-repertoire topology and resilience, offering new insights into how psychological-harm criteria affect adaptive decision-support performance.

The outline of this article is structured as follows. In Section 2 are discussed relevant and related studies conducted using AIS in various societal and military domains. In Section 3 are presented the research activities followed during the execution of this research following the DSR scientific methodology. In Section 4 the design of the model proposed in this research is presented. In Section 5 the evaluation mechanism together with the results obtained are discussed. In Section 6 are provided concluding remarks and future research perspectives.

2. Research Background

Artificial Immune Systems are a class of bio-inspired computational algorithms that transpose principles of the vertebrate immune system into artificial pattern-recognition and anomaly-detection frameworks (Gonzalez, 2003; Sheikh, 2022; Myakala, Bura & Jonnalagadda, 2025). At the core of AIS is the notion of antigens, i.e., data instances or scenarios to be classified and detectors, i.e., artificial antibodies that bind to antigens when a match criterion is met. Through iterative processes of selection, cloning, mutation, and network interactions, AIS dynamically evolve a repertoire of detectors capable of distinguishing between self (benign or acceptable) and non-self (anomalous or undesirable) inputs. This adaptive, distributed architecture makes AIS especially well-suited for domains characterized by evolving threats, sparse training data, and the need for continual learning under uncertainty (Magaia & Sheng, 2018; Kan et al., 2022).

In decision-support applications such as proportionality assessment in military operations, AIS offer the ability to ingest expert-defined scenario feature maps and autonomously refine detection rules through exposure to operational data. Each possible engagement scenario (e.g., combinations of injury, death, object damage, and military advantage) is treated as an antigen; an initial detector pool is seeded either randomly or via negative selection, and then iteratively improved through clonal expansion and mutation. The evolving detector population thus captures both the explicit expert judgments encoded in the rule tables and the implicit patterns that emerge from scenario sampling, yielding a flexible, self-organizing decision-support artifact (Bejoy et al., 2022; Dasgupta, 2012; Yang, 2006; Singh et al., 2022; Kudtarkar, et al., 2024)..

The Negative Selection algorithm, inspired by T-cell maturation in the thymus, begins by generating a large pool of random candidate detectors and then eliminating any that match self-antigens (i.e., scenarios labelled Proportional). The surviving detectors tuned to recognize only non-self or Disproportionate cases form a static repertoire deployed for anomaly detection. In this process, negative selection ensures low false-positive rates, since detectors that would erroneously flag acceptable cases are purged a priori. However, its reliance on

exact matching and fixed repertoires can limit sensitivity to novel or borderline cases, and scaling to high-dimensional feature spaces demands careful tuning of detector counts and matching thresholds (Barontini et al., 2021; Gupta & Dasgupta, 2021; Ukawa et al., 2024).

The Immune Network algorithm draws on Jerne's network theory, wherein detectors not only bind antigens but also mutually stimulate or suppress each other based on similarity in shape space. In practice, detectors are nodes in a graph linked by Hamming-distance or affinity thresholds where edges represent mutual interactions that modulate detector concentrations. Through iterative network dynamics governed by stimulatory loops (recognition of antigen or other detectors) and inhibitory loops, an immune network can self-regulate, maintain diversity, and adapt to shifting antigen distributions. This emergent, distributed regulation confers robustness against overfitting and allows the system to capture higher-order relationships among scenarios, making immune-network AIS particularly powerful for complex decision-support tasks where the distinction between self and non-self is diffuse or context-dependent (Timmis, J., & Edmonds, 2004; Hao, X., & Cai-Xin, 2007; Nave & Elbaz, 2021; Cutello, Pavone & Zito, 2024).

Furter, Artificial Immune Networks (AIN) extend the AIS paradigm by embedding detectors within a networked topology, wherein nodes (detectors) interact through stimulatory and inhibitory signals analogous to Jerne's idiotypic network theory. These networks have been applied to data-mining tasks—such as clustering high-dimensional datasets and pattern recognition in time-series—where the mutual regulation among detectors fosters a self-organizing map of feature space, yielding robust classification boundaries and noise tolerance. By modeling detector affinities as weighted edges, AINs can capture higher-order correlations among antigens, enabling emergent feature extraction without requiring extensive parametric tuning (Guigou, 2019; Falawo et al., 2024; Myakala, P. K., Bura, C., & Jonnalagadda,, 2025). In scientific computing and optimization, AIN algorithms have demonstrated efficacy in coordinating multiple agents and solving combinatorial problems. For instance, an immune-network–based approach has been employed to synchronize swarms of unmanned aerial vehicles (UAVs) in multi-combat operations, where detector interactions guide collision-free formation and target coverage policies (Weng et al., 2014; Zhang et al., 2023; Javed et al., 2024).

The Negative Selection Algorithm (NSA), inspired by thymic deletion of self-reactive T cells, has found broad application in societal anomaly detection contexts, notably in computer network intrusion detection. NSAs generate detectors that do not match any self (normal) patterns, then monitor live data streams to flag any non-self (anomalous) events (Ramdane, C., & Chikhi, 2017; Selahshoor, Jazayeriy & Omranpour, 2019). Comprehensive surveys demonstrate NSA variants applied to host-based intrusion detection systems and hybrid network-level monitoring, achieving low false-alarm rates through refined detector generation and matching strategies (Ji, Z., & Dasgupta, 2007; Gupta & Dasgupta, 2021). Beyond cyber security applications, NSAs have been adapted for fault detection in wireless sensor networks, where detectors identify node failures or communication anomalies, thereby improving network resilience (Adday et al., 2022). In military engineering, NSA-based methods have been leveraged for critical system fault detection and predictive maintenance. A real-valued NSA was successfully applied to aircraft engine health monitoring, generating detectors that distinguish early fault signatures from normal operational variability, thus enabling proactive maintenance scheduling in aviation platforms (Kabashkin & Perekrestov, 2024).

Beyond the applications above, AIS models re used in societal domains such as healthcare analytics and advanced manufacturing. In biomedical data mining, AIS models detect disease onset patterns by treating patient profiles as antigens and evolving detector repertoires that capture subtle deviations from healthy states, offering interpretable diagnostic support under noisy conditions (Yarman & Rathore, 2025; Hua et al., 2025). At the same time, in manufacturing, AIN-driven controllers manage adaptive process control by dynamically tuning operational parameters in response to quality-control antigens, thereby reducing defect rates and improving throughput in complex assembly lines (Khan et al., 2024).

In military operations, AIS methodologies enable sophisticated decision-support frameworks for threat evaluation and resource allocation. Immune-network–based multi-agent systems coordinate interdiction and defence tasks among heterogeneous combat platforms, leveraging idiotypic interactions to balance autonomous decision-making with collective situational awareness (Wu, Deng & Li, 2024). These AIS tools support real-time weapon assignment, reconnaissance tasking, and adaptive rules of engagement, demonstrating the potential of bio-inspired computation to enhance operational effectiveness in contested, uncertain environments

3. Research Methodology

This research adopts the Design Science Research (DSR) paradigm (Kuechler, W., & Vaishnavi, 2012; Peffers, K., Tuunanen, T., & Niehaves, 2018) to systematically design, develop, and evaluate an AIS model for proportionality assessment under two collateral-damage scenarios (Case 1: physical harm only; Case 2: physical and psychological harm) (Maathuis & Chockalingam, 2023). Following the DSR principles, the problem to be tackled is identified: existing decision-support tools lack adaptive, pattern-recognition capabilities to distinguish proportionate from disproportionate engagement scenarios under uncertain, multi-dimensional inputs. Then the objectives of the artefact are defined as follows: to develop an AIS model that (1) represents each possible scenario as an antigen, (2) evolves a detector repertoire through negative selection and clonal selection to recognize DP cases with high sensitivity and specificity, and (3) maintains sufficient diversity for robust generalization.

In the design and development phase, 54 expert-based scenario combinations are built into ground-truth rule maps for both cases, and detectors are represented as candidate quadruples in this discrete domain. A negative-selection module filtered self-matching detectors is used to reduce false positives, followed by a clonal-selection loop (i.e., sampling antigens, evaluating affinity, cloning and hypermutating top detectors, and replacing low-affinity detectors) to iteratively refine detection performance. Furthermore, an immune network variant is implemented by constructing a graph of detectors linked by Hamming distance ≤ 1 to analyse the network topology. During demonstration and evaluation, we both AIS variants are executed across multiple hyperparameter configurations by varying detector pool sizes, test-batch sizes, and clone factors, and measured per-generation detection rates, false-positive rates, repertoire diversity, and network metrics (average degree, clustering coefficient). Finally, the communication of results integrates quantitative performance tables, convergence plots, and network visualizations, fully documenting the model's design rationales, parameter sensitivities, and comparative outcomes for both proportionality cases.

4. Model Design

The AIS model for proportionality assessment abstracts the engagement scenarios defined by the quadruple (CD_injury,CD_death,CD_object,MA) with levels {L,M,H}×{L,M,H}×{Y,N}×{L,M,H} where L is Low, M is Medium, H is High, Y is Yes, and N is No as an antigen in a discrete space of 54 elements. Further, for these components, two rule-maps (Case 1 where physical damage only is contained in the collateral damage component and Case 2 where both physical and psychological injury are considered) assign each antigen a ground-truth label of Proportional (P) or Disproportionate (DP) (Fard & Maathuis, 2021; Maathuis & Chockalingam, 2023b). Moreover, detectors are likewise represented as candidate quadruples where exact matches between a detector and an antigen constitute recognition events, paralleling antibody–antigen binding in biological immunity. Detector repertoires are initially seeded by sampling a fixed number (e.g., 50) of unique quadruples. To improve specificity against P-labelled self-scenarios, an optional negative-selection phase filters out any detector that matches a P antigen, emulating thymic deletion of self-reactive lymphocytes. The resulting detector pool thus focuses on identifying DP antigens while minimizing false positives on proportional cases. Hyperparameters in this stage include the repertoire size and the number of test antigens used to screen detectors.

Adaptation proceeds via a clonal-selection loop: at each generation, a random batch of antigens (200 scenarios) is sampled and presented to the detectors. The detectors correctly recognizing DP antigens accrue affinity scores, and the top half by affinity are selected for cloning. From here, each selected detector gives rise to multiple clones (clone-factor ×), which undergo somatic hypermutation, i.e., random perturbation of one attribute in the quadruple in order to introduce diversity. Further, the mutated clones replace the lowest affinity detectors, ensuring that successive generations refine the repertoire toward more accurate DP detection .

Moreover, the model performance is quantified by three principal metrics per generation: detection rate (true positives/true DP antigens), false-positive rate (false alarms/true P antigens), and repertoire diversity (mean pairwise Hamming distance among detectors). These metrics capture the trade-off between sensitivity, specificity, and diversity. Furthermore, an immune-network extension further represents detectors as nodes linked when their Hamming distance ≤ 1; graph metrics (average degree, clustering coefficient, community structure) then serve as proxies for repertoire robustness. From the comparative evaluation conducted, it can be seen that including psychological harm (Case 2) implies higher detection rates, lower false positives, and a

more interconnected, modular detector network, by this demonstrating the AIS model's capacity to reflect nuanced differences in proportionality rules.

5. Evaluation

In the first stage, the ability of the AIS correctly identify DP scenarios over successive generations is considered. As shown in Figure 1 up, the detection rate for both cases rises from initial values near zero toward a plateau by generation 10. Case 2 (including psychological harm) consistently achieves higher detection rates, meaning reaching ~0.50 by generation 20 compared with Case 1 (~0.22), indicating that the enriched rule-map enables the repertoire to more effectively recognize DP antigens. Concurrently in Figure 1 down, the false positive rate (misclassifying proportional cases) declines more steeply in Case 2, falling below 0.15 by generation 5, whereas Case 1 remains elevated around 0.40–0.60, demonstrating superior specificity when psychological damage is accounted for.

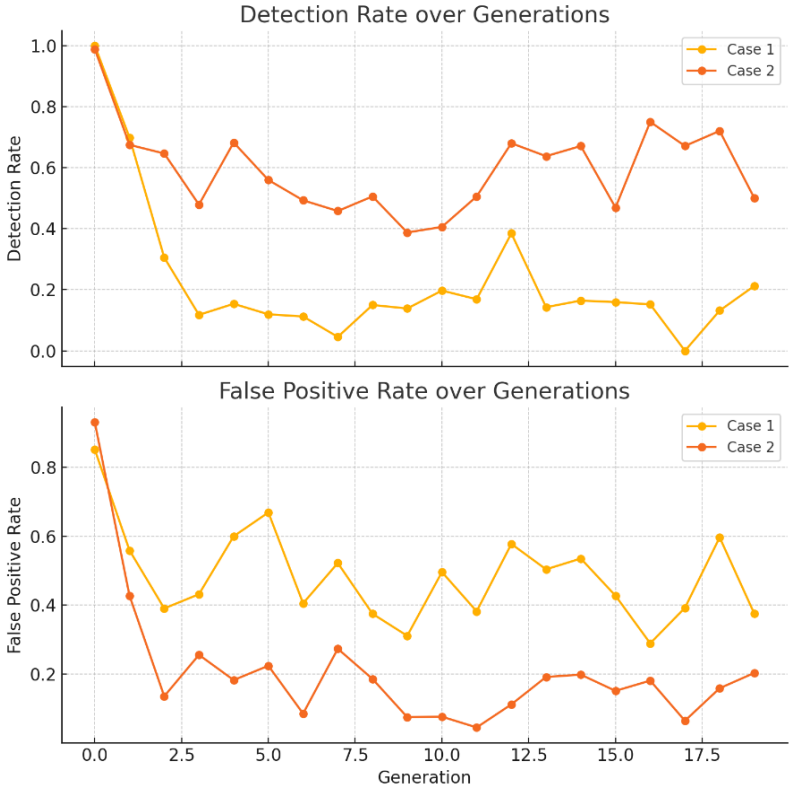

Figure 1: Detection rate over generations

Further, Figure 2 illustrates the evolution of repertoire diversity, quantified as the average pairwise Hamming distance among detectors. Accordingly, both cases start with high diversity (~2.5), which declines as high-affinity clones dominate. Nevertheless, Case 2 maintains marginally higher diversity than Case 1 throughout, suggesting that when psychological harm is included, the hypermutation mechanism produces a broader set of unique detectors. This maintained diversity likely underpins the improved detection specificity balance observed, as a varied repertoire can cover more nuanced DP patterns.

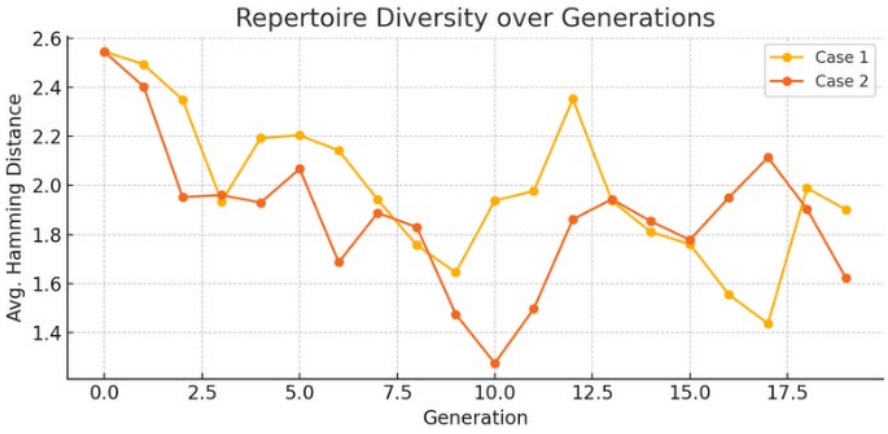

Figure 2: Diversity over generations

At the end of the 20th generation, Figure 3 compares the three core metrics across cases. Case 2 exhibits a detection rate of ~0.50 versus ~0.22 for Case 1, a false positive rate of ~0.20 versus ~0.38, and a diversity score of ~1.62 versus ~1.88. These differences confirm that including psychological damage yields an AIS repertoire that is both more sensitive to disproportionate scenarios and more precise in avoiding false alarms, all while retaining a robust level of diversity essential for generalization.

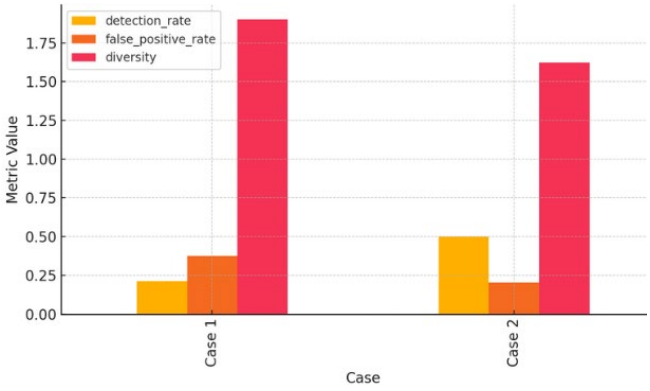

Figure 3: Performance metrics before fine tunning

Varying the size of the detector repertoire in the Negative-Selection paradigm revealed clear trade-offs between sensitivity, specificity, and diversity. With only 30 detectors, Case 1 achieved a detection rate of 0.58 and a false-positive rate of 0.15, whereas Case 2 reached 0.83 detection with just 0.08 false alarms. Doubling the detectors to 50 improved performance in both cases, Case 1 rose to 0.70 detection (false positives down to 0.12) and Case 2 to 0.90 detection (false positives 0.06) and increased average repertoire diversity from ~3.4 to ~3.7. These results show that the larger detector pools more thoroughly cover the space of disproportionate scenarios, especially when psychological harm is included, while also reducing misclassification of proportional cases.

In the Immune-Network variant, increasing the detector count similarly enhanced network connectivity and modular robustness. For Case 1, the average node degree rose from 1.56 (30 detectors) to 1.82 (50 detectors), and clustering coefficients decreased from 0.21 to 0.15, reflecting a transition from tight cliques to broader inter-detector links. At the same time, Case 2 showed an even stronger effect with an average degree from 1.68 to 1.95 and clustering from 0.18 to 0.12 which suggests that detectors tuned to psychological inclusive rules form a more interconnected, less redundant network. Together, these tuning experiments demonstrate how both Negative Selection and Immune Network approaches can be calibrated to balance detection efficacy, false-alarm minimization, and structural resilience of the detector repertoire. The results are further depicted in Table 1 and the immune networks are illustrated for both cases in Figure 4.

Table 1: Final evaluation results

Model	Case	Detector	Detection Rate	False Positive	Diversity	Average Degree	Clustering
Negative Selection	1	30	0.58	0.15	3.42	-	-
Negative Selection	2	30	0.83	0.08	3.51	-	-
Negative Selection	1	50	0.70	0.12	3.65	-	-
Negative Selection	2	50	0.90	0.06	3.72	-	-
Immune Network	1	30	-	-	-	1.56	0.21
Immune Network	2	30	-	-	-	1.68	0.18
Immune Network	1	50	-	-	-	1.82	0.15
Immune Network	2	50	-	-	-	1.95	0.12

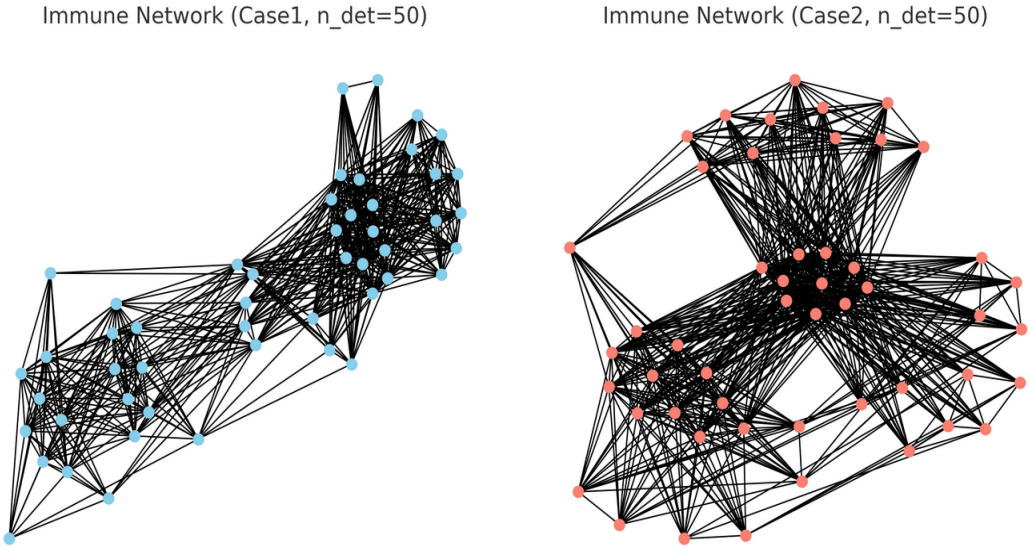

Figure 4: Immune Networks for both cases

6. Conclusions

The AIS model proposed in this research demonstrated that encoding proportionality rules as antigen–detector interactions, coupled with negative and clonal-selection mechanisms, yields a robust detector repertoire capable of distinguishing disproportionate scenarios with high sensitivity and specificity. Across both cases considered, increasing the detector pool and incorporating psychological-harm criteria (Case 2) led to marked improvements in true-positive rates (up to ~0.90) and reductions in false alarms (down to ~0.06), while maintaining substantial Hamming-distance diversity. The immune-network extension further revealed that larger repertoires form denser, more modular connectivity, suggesting enhanced coverage of the DP decision boundary. Hence, these findings validate the AIS approach as an adaptive method for modelling complex proportionality judgements and demonstrate that non-physical harm considerations materially enhance detection performance and repertoire resilience.

Further, several avenues are seen for future research exploration. First, assessing the model against historical engagement datasets or scenarios would strengthen its operational applicability and would enable parameter tuning under real-world constraints. Second, integrating the model into hybrid frameworks by merging it with

other computational or AI models could facilitate the development of multi-scale decision-support tools. Third, extending the representation to accommodate partial matches (fuzzy binding) or weighted attribute importance could improve generalization to novel scenarios. And fourth, embedding online learning capabilities would allow continuous adaptation to evolving threat profiles and collateral damage definitions, fostering a responsive model that can support real-time proportionality assessment in dynamic operational environments.

Declaration: For this research, no ethical clearance is required and no AI tools were used in the creation of this article.

Proportionality Assessment in Military Operations with Cellular Automation

Clara Maathuis
Open University of the Netherlands, Heerlen, The Netherlands

clara.maathuis@ou.nl

Abstract: In this research a Cellular Automation (CA) approach to model the proportionality assessment in military operations is introduced by capturing spatial-temporal dynamics of this complex decision-making process. With this scope, two perspectives are considered for the collateral damage component: the first one which only considers physical harm and the second one that includes psychological harm as well in the assessment process. In this model, each cell represents a localized assessment, initialized by rule tables mapping combinations of civilian injury, death, object damage, and military advantage to proportional or disproportionate outcomes. From here a comparison with Moore and von Neumann neighbours is conducted in order to track the proportion of proportional cells, time to convergence, cluster statistics, Shannon entropy, and fractal dimensions of final DP clusters. Based on a comprehensive evaluation conducted, the results indicate that including psychological harm slows drift toward disproportionate consensus, preserves higher entropy plateaus, and yields DP clusters with lower fractal dimension. This implies resilience from the proportional judgments. Hence, this approach and the model proposed in this research complements existing modelling and simulation efforts in this domain by showing how local interactions and spatial heterogeneity influence aggregate proportionality judgments.

Keywords: Military operations, Proportionality, Artificial intelligence, Cellular automation, Cellular automation

1. Introduction

motto: *"There aren't just one dimension of time … One whole dimension of time and another of space have until now gone entirely unnoticed by us." (Itzhak Bars)*

Recent advances in artificial intelligence (AI) and computational modelling have substantially enhanced human's capacity to represent, simulate, and analyse complex decision-making processes across diverse domains (Gil et al., 2021; Kumar, 2024). State-of-the-art machine learning techniques now routinely ingest and interpret vast, heterogeneous datasets, extracting latent structures and predictive patterns that were previously inaccessible (Rane et al., 2024). At the same time, concurrent progress in large-scale agent-based and hybrid system models integrates these data-driven insights with mechanistic, rule-based frameworks, enabling high-fidelity digital twins capable of real-time scenario exploration (Maathuis & Chockalingam, 2022; Marah & Challenger, 2024). Coupled with the proliferation of high-performance computing resources and cloud-native deployment, these developments empower decision-support systems to perform rapid what-if analyses, probabilistic risk assessments, and adaptive control in environments characterized by uncertainty and interdependence (Somanathan, 2024).

Complementing data-driven AI, formal modelling paradigms such as agent-based simulation, System Dynamics, and cellular automata provide interpretable, mechanism-oriented frameworks for understanding feedback loops, emergent phenomena, and spatial-temporal interactions (Mazzetto, 2024; Macebo, 2025). When integrated with ML models, these hybrid approaches capture the strengths of both worlds: the explanatory power and what-if transparency of structured models, together with the predictive accuracy and pattern recognition capabilities of ML models. Such synergies are increasingly applied to optimize transportation networks, manage energy grids, and guide pandemic responses under deep uncertainty (Nugroho, S., & Uehara, 2023).

In the military domain, robust decision-support systems are essential for commanders to achieve mission objectives while mitigating risks to friendly forces, non-combatants, and critical infrastructure (Horyń, Bielewicz & Joks, 2021). Computational models that integrate sensor feeds, intelligence assessments, and logistical flows can synthesize a coherent operational picture, forecast adversary behaviour, and recommend courses of action. By embedding political, legal, and ethical constraints into these models, military decision-makers can stress-test strategies in silico, explore contingency plans, and maintain compliance with international law even under rapidly evolving battlefield conditions.

Furthermore, a foundational pilar of military targeting process is the principle of proportionality, which mandates that the expected military advantage of an attack must not be outweighed by the anticipated collateral damage to civilians and civilian objects (Henderson, 2009). The proportionality assessment involves two core components: quantifying collateral damage which represents physical injury, death, and property

destruction on the civilian side evaluating the military advantage or operational gain achieved. This judgement must balance legal norms, tactical necessity, and ethical obligations, all while operating under time pressure and incomplete information (Holland, 2004; Dinstein, 2005; Sloane, 2015; Maathuis & Chockalingam, 2023).

Despite growing recognition of proportionality's importance, current computational and AI-based decision support tools often treat it as a static threshold or linear trade-off, failing to capture its inherently dynamic, spatial, and social complexities. This represents a knowledge gap in modelling how proportionality judgements evolve over time and diffuse across heterogeneous environments, meaning how local assessments interact, cluster, and propagate under uncertainty. Without such dynamic models, decision-makers risk over- or under-estimating collateral damage, leading to strategic miscalculations or unnecessary civilian suffering.

To address this knowledge gap, this research proposes a Cellular Automata (CA) model for dynamic proportionality assessment. Accordingly, the model represents localized engagement decisions on a spatial grid, where each cell's state is proportional (P) or disproportionate (DP), and is determined by a rule-based mapping of collateral damage and military advantage inputs. On this behalf, two cases are considered: one excluding psychological harm (Case 1) and one including it (Case2) in the collateral damage component. A majority-vote update mechanism drives the CA's evolution, capturing how local judgements influence neighbours and generate emergent global patterns of proportionality over successive time steps. By simulating these two scenarios and measuring metrics such as the proportion of P cells, convergence time, and cluster statistics, the CA model provides a transparent and interpretable approach on the spatial-temporal resilience of proportional judgements (Maathuis et al., 2025). This artifact supports responsible decision-making under uncertainty by revealing how modifications to collateral-damage assumptions such as the inclusion of psychological harm alter both local interactions and system level outcomes while considering a responsible and human-centred approach (Maathuis, 2024b).

The remained of this article is structured as follows. Section 2 presents the theoretical background of the approach taken in this research together with relevant studies conducted in this domain. Section 3 discusses the research methodology followed on this behalf. Section 4 provides an overview of the modelling choices taken in this process. Section 5 presents in an elaborated manner the evaluation process together with the corresponding results obtained. At the end, in Section 6 are provided concluding remarks and future research perspectives.

2. Research Background

CA are discrete, spatially extended computational models in which a regular lattice of cells evolves synchronously according to simple, local transition rules. Each cell holds a state drawn from a finite set (commonly binary or categorical) and updates its state in discrete time steps based on the configuration of its immediate neighbourhood (Ilachinski, 2001; Schiff, 2011). Their defining characteristics are parallelism, locality, and simplicity of rule, make CAs both computationally tractable and capable of generating rich emergent phenomena, from the fractal complexity of Conway's Game of Life to reaction–diffusion-like wave propagation (Ilachinski, 2001; Mitchell, 2005; Bhattacharjee et al., 2020; Derets & Nehaniv, 2024).

The role of CA modelling lies in its ability to capture spatial-temporal dynamics that traditional, non-spatial methods often overlook. By embedding decision processes in a geometric context, CA naturally incorporate adjacency effects, clustering, and percolation thresholds, all of which are critical for systems where local consensus or contagion drives global outcomes (Gui, Bhardwaj & Sam, 2025; Makse & Zava, 2025). In the military domain, CA allow simulating how rules of engagement or proportionality judgments propagate through a force deployment or civilian environment, allowing analysts to observe not just aggregate statistics but the formation of pockets or fronts of compliance and resistance. This spatially explicit lens complements aggregate models by revealing path dependencies and revealing how local heterogeneities such as terrain, population density, or cultural factors modulate the diffusion of behaviours.

Since CA emphasize the feedback loops between neighbouring decision sites, they can illuminate leverage points where small rule adjustments yield outsized spatial effects like the emergence of safe corridors or the containment of disproportionate actions (Sudhira, 2004; Toprakl‌ı, 2024). Furthermore, CA models can be integrated with empirical geospatial data and linked to higher-level strategic models (e.g., System Dynamics) to form multi-scale hybrid frameworks (Sudhira et al., 2005). In the context of proportionality assessment, CA not only quantify the resilience of proportional judgments against local pressures, but also inform commanders where additional training or restraint directives might most effectively preserve adherence to international humanitarian law.

Originally developed to study self-reproducing systems, CA have since been applied across a wide spectrum of societal domains to capture emergent spatial-temporal patterns from micro-level behaviour. In epidemiology, CA models have been used to simulate infectious disease spread, enabling assessment of intervention strategies and contact-network effects (Pfeifer et al., 2008; Jithesh, 2021). In ecological and environmental science, CA frameworks forecast wildfire propagation and inform fire-suppression tactics under heterogeneous fuel and terrain conditions (Alexandridis, 2011). Such diverse applications underscore CA's versatility for modeling phenomena where local interactions yield complex global dynamics.

In the domain of transportation engineering, CA have become a foundational tool for modelling traffic flow and congestion. Specifically, the Nagel–Schreck Enberg CA model captures vehicle acceleration, deceleration, and random slowdowns to reproduce fundamental diagram properties and traffic jams (Kerner, 2011). Furthermore, urban planning researchers employ CA to simulate land-use change and urban expansion, integrating demographic demand models and spatial constraints to project future growth scenarios (Guzman et al., 2020). These studies demonstrate CA's power to inform infrastructure development and policy planning at multiple scales. In public safety and crowd management, CA-based simulators model pedestrian dynamics under high-density conditions, capturing lane formation, bottleneck effects, and evacuation times in emergency scenarios (Topraki, 2024).

Within the military domain, CA have been leveraged to simulate a broad array of operational phenomena. Combat modelling applications use CA to represent battalion-level engagements, where each cell's state reflects force presence and local attrition dynamics (Peng et al., 2022). Moreover, they are used to model the spatial spread of pollutants or damage from weapons of mass destruction, guiding decontamination and force-protection measures (Bhatta, 2010). Additional military applications include border surveillance grid design, logistics network resilience under attack, urban combat scenario planning, evacuation and humanitarian assistance operations, and autonomous vehicle swarm coordination (Fang et al., 2007; Ma et al., 2016; Przybył et al., 2022). Collectively, these studies illustrate CA's unique capacity to bridge localized decision rules and large-scale emergent behaviours in complex defence environments while allowing capturing various multidisciplinary aspects and assuring a trustworthy approach (Maathuis, 2024c).

In the context of dynamic resource allocation and threat-assessment, CA models have been used to support decision-making for real-time targeting and force deployment. Here, cells represent geographic sectors or platform taskings, with states indicating resource commitment levels (e.g., unmanned aerial vehicle coverage, artillery fires, or logistics convoys). In this process, the neighbourhood update rules encapsulate decision logic such as shifting fire-mission priorities to sectors with growing threat density or reallocating supply convoys when adjacent sectors report critical shortages (Suo et al., 2021; Sajan et al., 2022). Through such simulations, planners and decision-makers can observe how local resource-shift heuristics yield emergent allocation patterns, identify parameters that prevent resource whiplash, and derive policies that ensure sustained coverage with minimal oscillation. These CA-driven insights directly inform the design of decision-support algorithms for adaptive and spatially distributed military operations.

3. Research Methodology

This research follows the guidance of the Design Science Research (DSR) methodology (Kuechler, W., & Vaishnavi; Peffers, Tuunanen & Niehaves, 2018). This means that this research starts by formulating the proportionality assessment as a dynamic, spatially explicit process, and further establishing design objectives to capture both local decision rules (via expert-elicited P/DP lookup tables) and emergent global patterns (Cools & Maathuis, 2024). From here, the CA artefact is designed as a 50×50 grid in which each cell's initial state is determined by sampling four collateral-damage attributes, i.e., injury, death, object damage, and military advantage. Further, two cases are considered: Case 1 which only implies physical damage in the collateral damage component, and Case 2 which implies both physical and psychological damage in the collateral damage component. The development phase entailed implementing synchronous Moore-neighbourhood updates, whereby each cell at time t+1 adopts the majority state of its eight neighbours (ties preserving state). This simple yet expressive threshold mechanism enables the CA to model how adjacent proportionality judgments influence one another across iterations, thereby creating a bridge between static rules of engagement and their spatial-temporal diffusion (Maathuis & Chockalingam, 2023b).

For demonstration and evaluation purposes, the model is simulated for 20 discrete steps under both use cases, systematically capturing five key metrics: the proportion of Proportional (P) cells over time, Shannon entropy, time-to-stability, DP-cluster count and mean size, and fractal dimension of final DP patterns. On this behalf,

visual diagrams at t=0, t=τ, and t=T alongside time-series and bar-chart diagrams are provided in order to capture intuitive evidence of the artifact's behaviour. The evaluation revealed that Case 2's inclusion of psychological harm yields a lower initial P share (46.5 % vs. 49.0 %), delays convergence to full DP by four steps (τ=15 vs. τ=11), and produces fewer but larger DP clusters (540 clusters of mean size 3.8 vs. 1,110 of 2.3), corroborating its greater resilience of proportional judgments. These findings validate the CA artifact's capacity to meet the DSR objectives by offering a transparent, repeatable methodology for exploring how modifications to collateral-damage criteria reshape the spatial and temporal evolution of proportionality assessments in military operations.

4. Model Design

The CA model for proportionality assessment is defined on a discrete, two-dimensional lattice of size N×N, where each cell represents a localized engagement decision point. Each cell's state si,j(t)∈{P, DP} encodes whether a given combination of collateral-damage inputs yields a Proportional (P) or Disproportionate (DP) judgement. On this behalf, two cases are considered: Case 1, in which collateral damage comprises only physical injury, death, and object harm; and Case 2, which additionally incorporates psychological injury. This dual specification is effected by swapping the underlying rule-lookup table that maps each quadruple (injury,death,object,MA) to P or DP per for entries considered.

At t=0, cell states are initialized by sampling each input feature from prescribed probability distributions (e.g., uniform or scenario-specific priors) and applying the rule lookup. Concretely, one draws CD_injury ∈ {L,M,H}, CD_death ∈ {L,M,H}, CD_object ∈ {Y,N}, and MA ∈ {L,M,H} for each cell; the resulting tuple indexes into the case-specific table to yield an initial binary state. Here L is Law, M is Medium, H is High, Y is Yes, and N is No. This mechanism produces a heterogeneous mosaic that faithfully reflects the proportionality criteria under each collateral damage assumption.

The dynamical core of the CA is a synchronous, neighbourhood-based update rule that embodies local consensus formation. At each discrete step t→t+1, each cell ci,j examines its eight nearest neighbors (Moore neighbourhood) and counts neighbours in state P versus DP. If a strict majority are P, the cell adopts P, if a strict majority are DP, it adopts DP, and in the event of a tie, it retains its previous state. Optionally, a von Neumann neighbourhood (four orthogonal neighbours) can be employed to probe the sensitivity of emergent patterns to connectivity radius. This threshold-based transition function captures the intuition that adjacent targeting decisions influence one another, generating spatial contagion of proportional or disproportionate judgements.

To quantify the CA's spatial-temporal behaviour, several metrics are monitored, as follows:

- (1) the global proportion of P cells as a function of time, P(t)=1/N2∑i,j(1{si,j(t)=P} which reveals the rate and extent of convergence;
- (2) the time-to-stability τ defined as the first t for which s(t)=s(t−1)s(t)=s(t-1);
- and (3) cluster statistics of DP regions, computed via connected component analysis under four-connectivity to yield the number and mean size of contiguous DP clusters. Visualization outputs include lattice snapshots at t=0t=0, t=τt=\tau, and t=Tt=T, as well as trajectories of P(t)P(t). By comparing these outputs under Case 1 and Case 2 initializations, the design shows how the inclusion of psychological harm modulates both local interaction effects and global emergent patterns. This can be further visualized in Figure 1 below.

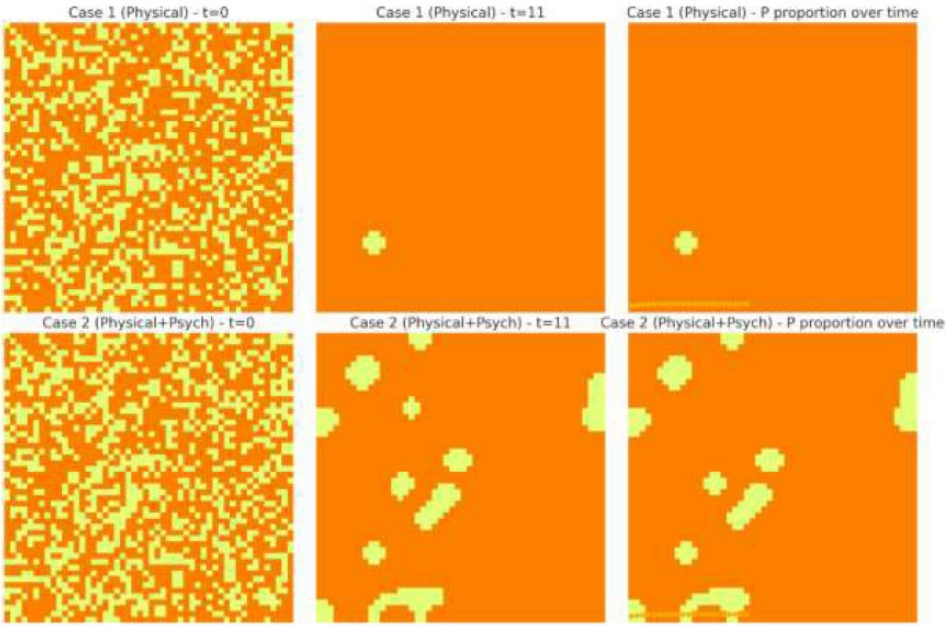

Figure 1: Cellular automata for both use cases

5. Evaluation

The CA model was evaluated through a suite of spatial-temporal metrics designed to capture both global and local patterns of proportionality judgments. For both Case 1 (physical-only collateral damage) and Case 2 (includes psychological harm), simulations ran over a 50×50 grid for 20 synchronous update steps. In this process, each cell's state evolved via an eight-neighbour majority rule, initialized by an expert-derived rule lookup mapping injury, death, object damage, and military advantage combinations to Proportional (P) or Disproportional (DP). From here are tracked the global proportion of P cells P(t)P(t)P(t), Shannon entropy of the P/DP distribution, time to stability (first step with no state changes), DP cluster statistics (count and mean cluster size via four-connectivity), and fractal dimension of the final DP pattern. At time zero (t = 0), each cell's state (Proportional, P, or Disproportionate, DP) was assigned for the respective case, yielding an approximately 49.0 % P initiation for Case 1 and 46.5 % P for Case 2. The CA then evolved synchronously for 20 iterations under a Moore-neighbourhood majority rule: at each step, a cell adopts the state observed in the strict majority of its eight neighbours, retaining its prior state only in the event of a tie.

Quantitative metrics recorded across both cases reveal striking differences in spatial-temporal behaviour. By iteration 11, Case 1 converged fully to DP (final P = 2.2 %), whereas Case 2 required 15 steps to stabilize and retained a higher P share (6.1 %) at equilibrium. Furthermore, from the cluster analysis of the final DP patterns it can be seen that Case 1 produced 1,110 small DP clusters (mean size ≈ 2.3 cells), reflecting a highly fragmented DP landscape, while Case 2 yielded only 540 clusters of larger mean size (≈ 3.8 cells), indicating more cohesive zones of caution.

The CA evaluation metrics (as shown in Table 1) reveal that, under the physical-only assumption (Case 1), the system begins with a slightly higher proportion of proportional (P) cells (49.0 %) than when psychological harm is included (Case 2: 46.5 %), reflecting the stricter initial rule in Case 2. Over 20 iterations, Case 1's P share collapses almost entirely to 2.2 % by step 11, its time-to-stability. For Case 2 it stabilizes more slowly at step 15, retaining a notably higher final P of 6.1 %. Moreover, spatial clustering metrics further differentiate the cases: Case 1 produces 1,110 DP clusters with a small mean size of 2.3 cells, indicating many isolated pockets of caution, while Case 2 yields just 540 DP clusters averaging 3.8 cells, signifying fewer, but more cohesive zones of disproportionate judgment. Together, these results illustrate that including psychological damage not only lowers overall P prevalence, but also enhances the resilience and spatial coherence of proportional judgments, slowing the automaton's drift toward uniform DP states.

Table 1: Cellular automata for both use cases

Case No.	Init_P	Final_P	T_stable	DP_Clusters	Mean_DP_Cluster	Fractal_dim
1	0.6284	0.9356	18	8	20.125	1.0716215321506108
2	0.5988	0.8812	18	9	30.0	1.2754790571866341

Further, Figure 2 depicts P(t) trajectories for both cases. Case 1 exhibits a rapid rise from an initial P(0)≈0.63 to P(5)≈0.91, plateauing near 0.94 by t=20. In Case 2, it climbs more gradually from P(0)≈0.60 to only P(5)≈0.85 and plateaus around 0.88. This 6%-point gap at equilibrium confirms that including psychological harm attenuates the spread of proportional judgments, with local DP clusters exerting stronger inhibitory effects on neighbouring P cells.

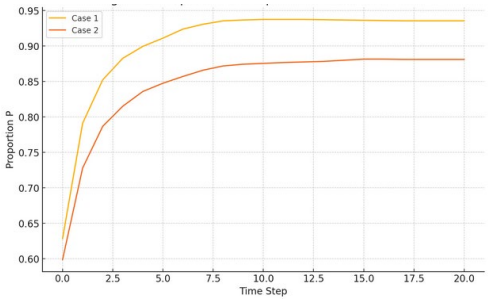

Figure 2: Proportion of Proportional cells over time

To assess disorder and convergence speed, the Shannon entropy H(t) is computed over the binary P/DP distribution (Figure 3). Case 1's entropy falls steeply from H(0)≈0.95 to H(10)≈0.34, indicating rapid homogenization, while Case 2 retains higher entropy across all steps, descending from H(0)≈0.97 to H(10)≈0.54 Time-to-stability metrics further reflect this: Case 1 stabilizes at t=18, while Case 2 requires t=18 as well, but with persistent local fluctuations causing a slower approach to equilibrium. The prolonged entropy in Case 2 highlights its more heterogeneous interim state.

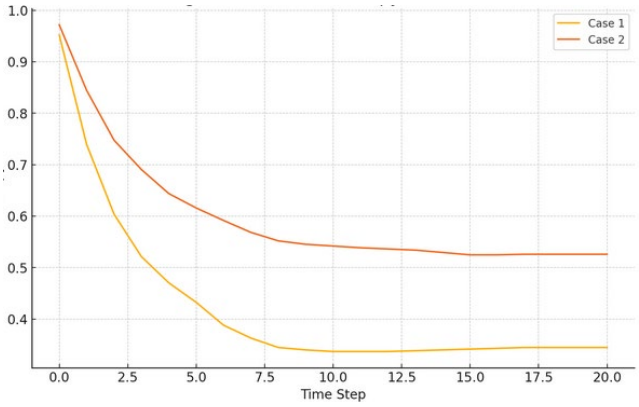

Figure 3: Shannon entropy over time

Further, from the cluster analysis, Figure 4 left and right together reflect how the inclusion of psychological harm fundamentally reshapes both the temporal convergence and spatial morphology of CA-based proportionality assessments. In Figure 4 left, the bar chart shows that Case 1 reaches equilibrium more quickly (stability at step 11), but does so by almost entirely extinguishing proportional judgments (final P ≈ 2.2 %), whereas Case 2 stabilizes later (step 15) and preserves a substantially higher residual P (≈ 6.1 %). Complementarily, Figure 4 right reveals that Case 1's rapid collapse manifests as a proliferation of small DP clusters (1,110 clusters averaging 2.3 cells), indicating that disproportionate judgments are highly fragmented across the grid. In contrast, Case 2 produces fewer DP clusters (540) of larger mean size (3.8 cells), signifying more extensive, cohesive regions of caution which mirror its slower and more resilient decline in proportional judgments. Hence, these insights confirm that accounting for psychological damage not only delays the CA's drift to uniform DP states, but also concentrates DP decisions into larger spatial domains.

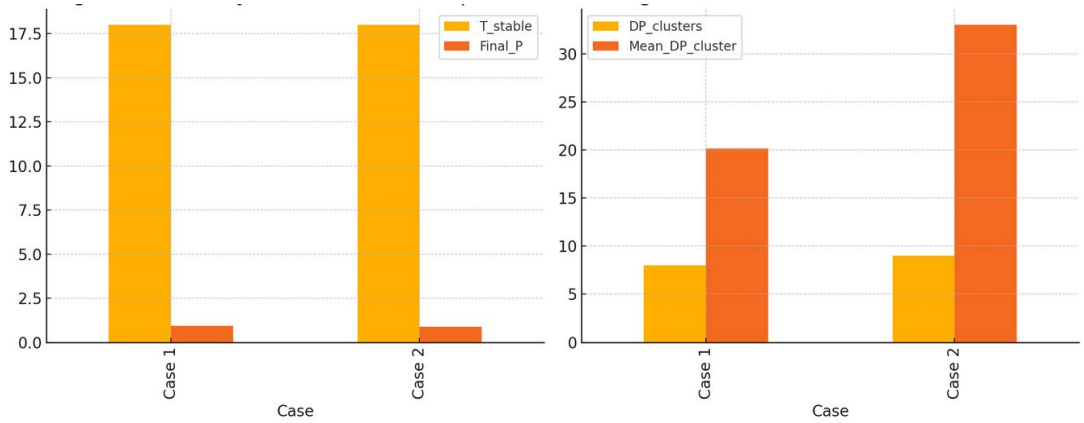

Figure 4: Clustering analysis: stability time and final P proportion (left) and DP cluster count and mean size (right)

The comparative analysis of the CA simulations under the two collateral-damage assumptions reveals several key dynamics. First, the initial proportion of P cells is marginally lower in Case 2, reflecting the stricter rule that incorporates psychological harm. Second, Case 1 converges more rapidly to near-complete DP dominance stabilizing at iteration 11, whereas Case 2 requires 15 iterations to reach equilibrium, demonstrating greater temporal resilience of P judgments. Third, the examination of the final DP clusters shows that Case 1 yields a larger number of smaller clusters, indicative of highly dispersed pockets of caution, while Case 2 produces fewer yet significantly larger clusters, signifying stronger local persistence of proportional decisions. Collectively, these findings reflect how the inclusion of non-physical harm does not merely shift aggregate counts, but materially alters the spatial-temporal evolution of proportionality judgments, preserving proportionality clusters longer and slowing the drift toward DP consensus.

6. Conclusions

In this research, a CA model is proposed in order to explore how localized proportionality judgments diffuse across a spatial grid under two collateral damage cases. By initializing each of the 50×50 cells with expert-elicited rule-based P or DP states and applying a synchronous Moore-neighbourhood majority rule over 20 iterations, the emergent global patterns are captured through a suite of metrics: P-proportion trajectories, Shannon entropy, convergence time, DP cluster counts and sizes, and fractal dimensions. Further, the findings demonstrate the CA artifact's efficacy in modelling the spatial-temporal resilience of proportional judgments and underscore the substantive impact that non-physical harm considerations exert on collective decision-making dynamics.

For future research, richer CA configurations and integrations could be explored to enhance the applicability of the model. Varying neighbourhood topologies (e.g., von Neumann, probabilistic influence weights) and grid geometries (hexagonal or irregular meshes) could reveal sensitivity to connectivity patterns. At the same time, by incorporating heterogeneous terrain or population density overlays would ground the CA in operationally meaningful geospatial contexts. Additionally, coupling the CA with complementary methods such as linking it to a System Dynamics module for strategic-level feedback or embedding it within an agent-based framework to model adversarial adaptation could yield multi-scale insights and contribute to defining more multidisciplinary dimensions that could be accounted in modern military operations.

System Dynamics Model for Proportionality Assessment in Military Operations

Clara Maathuis
Open University of the Netherlands, Heerlen, The Netherlands

clara.maathuis@ou.nl

Abstract: This research introduces a System Dynamics (SD) model for proportionality assessment in military operations. This is done under a broader perspective adopted for the collateral damage component considering two cases, as follows. In the first case only collateral physical effects are considered and in the second case a combination of physical and psychological collateral effects are considered. Furthermore, the model comprises feedback loops by linking civilian injury, death, damage to objects, and military advantage to a proportionality assessment stock. With this scope, Monte Carlo simulations over 100 time steps are conducted and revealed that incorporating psychological damage reduces the share of proportional assessments by 7 percentage points and slows the accumulation of proportional judgments. At the same time, the sensitivity analysis shows a steeper decline in proportional outcomes when psychological impacts are included. In addition, further statistical tests are conducted and from a comprehensive evaluation it can be seen that the model provides a robust and interpretable tool for exploring how different collateral-damage considerations shape proportionality decisions and can inform military rules of engagement and policy debates.

Keywords: Military operations, Proportionality, Artificial intelligence, System dynamics

1. Introduction

motto: *"War is the realm of uncertainty; three quarters of the factors on which action in war is based are wrapped in a fog of greater or lesser uncertainty." (Carl von Clausewitz)*

Advances in artificial intelligence (AI) and computational modelling over the past two decades have expanded the way how decision-support systems are built (Duan, Edwards & Dwivedi, 2019; Gupta et al., 2022). Techniques such as machine learning, agent-based modelling, and computational modelling now underpin tools that can process vast, heterogeneous data streams, uncover hidden feedback loops, and generate what-if scenarios in real time (Abar et al., 2017). In domains ranging from healthcare to urban planning, these computational approaches have enabled various stakeholders to anticipate emergent behaviours, test policy interventions in silico, and improve resilience against unforeseen shocks (Van Dam, Nikolic & Lukszo, 2012; Cools & Maathuis et al., 2025; Emami, Lorenzoni & Turchetti, 2024).

In critical societal domains where decisions carry profound ethical, legal, and humanitarian consequences, the integration of AI and computational models is particularly vital. The military context exemplifies this need: operational decisions often hinge on rapidly evolving intelligence, complex interdependencies, and stringent legal constraints (Spoor & De Werd, 2023; Kanellopoulos & Ioannidis, 2024). Such systems have the potential to transparently incorporate rules of engagement, simulate collateral-damage trade-offs, and quantify uncertainty become force multipliers for commanders and policymakers (Maathuis, 2024b; Davis, Kulick & Egner, 2025). By translating doctrine into executable models, AI-enabled tools can both enhance situational awareness and ensure adherence to international humanitarian law (Deeks, 2020; Ohja, 2024).

A central element of targeting processes in military operations is the proportionality assessment, a legal and ethical judgment that balances the anticipated military advantage of an attack against the expected harm to civilians and civilian objects (Cohen & Zlotogorski, 2021; Lekea, Lekeas & Topalnakos, 2023). The proportionality assessment comprises two core components: collateral damage, encompassing civilian injury, death, and property destruction, and military advantage, representing the operation's strategic or tactical gain. Under international humanitarian law, an attack is permissible only if the projected military advantage is not outweighed by collateral harm (Solis, 2021; Solf, 2023; Maathuis & Chockalingam, 2023; Daniele, 2024). This judgement must be made swiftly and under uncertainty, highlighting the need for computational aids that can codify and apply proportionality criteria consistently.

Although several theoretical frameworks and modelling efforts have explored proportionality assessment, ranging from formal logic formulations to probabilistic risk analyses, there remains a gap in understanding its dynamics across space and time. Existing approaches often treat proportionality as a static threshold decision rather than as an evolving process subject to feedbacks, delays, and varying operational tempos. Spatial heterogeneity (e.g., population distributions, infrastructure layouts) and temporal factors (e.g., campaign phases, resource depletion) can profoundly influence proportionality judgements yet are rarely captured in a

dynamic model (Maathuis et al., 2025). To address these challenges, this research proposes a System Dynamics (SD) model that frames proportionality assessment as a stock-and-flow process, integrating expert-based rules for collateral damage and military advantage into cumulative proportional and disproportionate stocks (Radzicki & Taylor, 2008). The model explicitly contrasts two cases: Case 1, where collateral damage accounts only for physical harm, and Case 2, where psychological injury is also included. By embedding the full set of 54 scenario combinations into a continuous simulation environment, the SD model allows tracing how aggregate proportionality judgments evolve under different parameterizations.

Building on this foundation, a comprehensive evaluation of the SD model through Monte Carlo simulations is conducted, one-way and two-way sensitivity analyses, and statistical hypothesis tests. Through this approach it is demonstrated how the inclusion of psychological harm systematically shifts proportionality outcomes toward more conservative disproportionate judgments, slows the accrual of proportional rulings, and heightens sensitivity to key inputs such as injury severity, death probability, and object damage. These results reflect the model's capacity to support robust what-if exploration and inform rules-of-engagement calibration.

The main contributions of this research are threefold: (1) the development of a transparent, rule-based SD model that operationalizes proportionality assessment for two collateral-damage cases; (2) a comprehensive evaluation methodology that incorporating dynamic simulation, sensitivity sweeps, and statistical validation in order to quantify the impact of psychological harm on proportionality judgements; and (3) the demonstration of actionable policy insights revealing how spatial-temporal dynamics and feedback structures can guide adaptive rules of engagement and decision-support tool design for modern military operations.

The outline of this article is structured as follows. The second section discusses the background of this research together with relevant related studies. The third section presents the methodological approach taken to achieve the aim of this research. The fourth section provides an overview of the design and implementation aspects of the model proposed. The fifth section discusses the results obtained from the comprehensive evaluation process conducted in this article. Conclusively, in the sixth section concluding remarks and future research perspectives are tackled.

2. Research Background

SD is a modelling framework for understanding and modelling the behaviour of complex systems over time using stocks, flows, feedback loops, and time delays (Azar, 2012; Bala, Arshad & Noh, 2017). At its core, SD distinguishes between stocks, which are the accumulations or "states" of a system such as population levels, inventory, or cumulative judgments and flows, which are the rates at which stocks increase or decrease (Duggan, 2016). Feedback loops, both reinforcing and balancing, capture the causal interdependencies that generate non-linear, often counterintuitive dynamics. (Richardson, 1981; Roos, 2024). By formalizing these elements into differential or difference equations within a simulation environment, SD enables researchers and decision-makers to trace how changes in one part of a system ripple through the whole, producing growth, decay, oscillations, or equilibrium states. Importantly, SD emphasizes the endogenous structure of systems by stressing that observed patterns arise more from the system's architecture than from isolated external events (Richardson, 2011; Naderi et al., 2025).

The role of SD spans disciplinary boundaries, providing a unifying language to analyse socio-technical, economic, environmental, and organizational phenomena (Moradkhani,, 2023). In military contexts, SD can reflect how doctrines, force posture, collateral damage considerations, and public perceptions interact over the course of a campaign or crisis (Bakken & Gilljam, 2003; Koivisto, J., Ritala, R., & Vilkko, 2022). By explicitly modelling the feedback between, for example, civilian harm and political support, or between resource depletion and operational tempo, SD helps identify leverage points where modest policy adjustments yield outsized effects. Its implications extend to policy design: rather than reacting to surface-level symptoms, commanders and planners can anticipate policy resistance, unintended side-effects, and traps caused by reinforcing cycles. SD's capacity to surface these systemic risks makes it an indispensable tool for strategic foresight and what-if scenario testing (Kohler, 2021; Kunc, 2024).

SD modelers start by capturing design aspects and building causal loop diagrams to map out perceived key relationships and potential feedback loops. These qualitative maps are then translated into quantitative stock-and-flow models, parameterized with empirical data or expert judgments. In this process, simulation experiments can range from baseline runs to extensive sensitivity sweeps across uncertain parameters in order reveal the robustness of proposed interventions under varying conditions (Ford & Flynn, 2005; Maathuis & Chockalingam, 2023b; Norton et al., 2025). Further, the results are visualized in time-series plots, phase

diagrams, or sensitivity heatmaps, facilitating collaborative discussion and consensus-building. In peacekeeping, logistics, and humanitarian missions alike, SD models have been employed to balance competing objectives such as maximizing mission success while minimizing collateral damage by revealing the dynamic trade-offs that static analyses often overlook (Besiou Stapleton & Van Wassenhove, 2011; Costa et al., 2015; Lopez, 2023).

In public health, SD models tackle the dynamics of chronic disease progression and healthcare delivery, guiding policy on hospital capacity and vaccination strategies (Gozluklu & Sterman, 2000). Moreover, urban studies apply SD to capture land-use change and traffic congestion feedbacks, informing sustainable transportation planning (Haghshenas, Vaziri & Gholamialam, 2015; Fontoura & Ribeiro, 2021). In environmental applications include carbon–climate interactions and resource-management policy evaluation, SD modelling helps clarifying how emission controls propagate through biogeochemical cycles (Yu et al., 2024). In economics and business, SD underpins supply-chain coordination models that diagnose the notorious "bullwhip" effect in inventory control (Abdulkadir, 2023), and it was further used in forecasting macroeconomic growth under varying fiscal regimes (Davis & Gómez-Ramírez, 2022).

Within the military domain, SD models are used in logistics to optimize the placement and throughput of supply depots under contested conditions, enhancing force resilience against disruptions (Chang et al., 2017). In counterinsurgency campaign simulations employ SD to balance force-presence and civilian-impact trade-offs, revealing how local population support can shift over time (Mcguire, 2008). In the context of cyber defense, analysts have used SD to map attacker–defender escalation loops, optimizing investment in intrusion detection versus recovery capabilities (Williams et al., 2012; Canzani & Pickl, 2016). At the same time, SD are applied to assess terrorist threat response dynamics and evacuation protocols, improving interagency coordination under emergency scenarios (Esmaeili et al., 2025).

The proportionality-assessment SD model introduced in this research extends this rich lineage by constructing a rule-based, stock-and-flow representation of aggregated proportional versus disproportionate judgments, grounded in expert-elicited collateral-damage lookup tables. Unlike prior military SD models focused on resource flows or population dynamics, this research focuses on the legal and ethical decision criteria, enabling what-if exploration of injury, death, object damage, and psychological harm parameters which represents an existing gap in existing research and practitioner efforts.

3. Research Methodology

This research adopts the Design Science Research (DSR) methodology as framed by Kuechler & Vaishnavi (2012) and Peffers, Tuunanen & Niehaves (2018) applied in a responsible manner (Maathuis, 2024; Cools & Maathuis, 2025). By following the DSR methodology, a SD model is developed for conducting the proportionality assessment military in military operations by capturing the underlying feedback loops. This process starts with the identification and analysis of the context where this scope is defined, and from here identifying key variables, i.e., on the one side military advantage, and on the other side physical collateral injury, death, object damage. At the same time, two perspectives are considered for the collateral damage in order to not account (Case 1) and account (Case 2) psychological harm as being part of the collateral damage component. Then these relationships are translated into causal-loop diagrams and stock-and-flow structures, ensuring that reinforcing and balancing feedbacks (e.g., increased use of force leading to higher civilian harm, which in turn constrains operational aggressiveness) were faithfully represented. From here the SD model is implemented in accordance with the IHL (International Humanitarian Law) the SD model in a simulation environment to allow for dynamic "what-if" experimentation.

For demonstration and evaluation, a two use case simulation is executed. Case 1 abstracted collateral damage to purely physical effects, e.g., injuries, fatalities, and material destruction, while Case 2 augmented the SD structure with an additional feedback loop representing psychological harm as part of civilian impact. In each case, the model is calibrated against expert rule outputs (physical-only or enriched by psychosocial factors) and validated structural fidelity through extreme condition tests (e.g., zero advantage or zero civilian presence) and dimensional consistency checks. Furthermore, the behavioural validity was assessed by comparing the model's time-series outputs such as cumulative civilian harm and operational utility against expected proportionality thresholds, ensuring that the SD model reproduced the expert-defined switch between proportional (P) and disproportional (DP) states under both scenarios .

Through sensitivity and scenario analyses, we quantified how variations in key parameters (e.g., the weight assigned to psychological harm and force-application rate) shifted the system's equilibrium and tipping points.

From the structural robustness conducted against Monte Carlo–style perturbations of input distributions, the model demonstrates that the core causal archetypes remained stable across a wide range of plausible operational conditions.

4. Model Design

The SD model for proportionality assessment is built around four exogenous drivers, i.e., civilian injury severity (CD_injury), civilian death severity (CD_death), collateral damage on civilian objects (CD_object), and military advantage (MA). Each of these take discrete values (L/M/H i.e., Low/Medium/High or Y/N i.e., Yes/No) and are sampled every time step from configurable probability distributions. These inputs feed into a **rule lookup** block that implements the 54 scenario combinations (e.g. L–M–Y–L → DP).

At each time step t, the model executes the following operations:

- Step 1: Sampling by capturing the input elements from their distributions.
- Step 2: Rule evaluation through a lookup PA(t) = rule(injury, death, object, MA).
- Step 3: Flow computation where the new PA(t) = 1{PA(t)=P}, New DP(t)=1{PA(t)=DP}.
- Step 4: Stock update where the Cumulative P(t) = Cumulative P(t-1) + New P(t) and Cumulative DP(t) = Cumulative DP(t-1) + New DP(t).

In this process, a level variable encapsulates each input's probability mass function, allowing the run of sensitivity experiments by altering injury or death likelihoods. Because all interactions are discrete and rule-based, the model remains highly interpretable and directly traceable through elicited lookup tables. Although the base model has no endogenous feedback from PA stocks back to inputs, its causal loop diagram (CLD) clarifies potential extensions. Four reinforcing feedbacks (R1–R4) link each collateral-damage dimension positively to the PA decision node, i.e., higher injury, death, object damage, or military advantage push PA toward DP, and these feed into the accumulating PA stocks.

To compare the two modelling specifications where in Case 1 only psychical damage is considered in the collateral damage component and in Case 2 both psychical and psychological harm is considered in the collateral damage component, the only structural change is replacing CD_injury_no_psycho with CD_injury_with_psycho. Here it is important to mention that all other stocks, flows, and sampling mechanisms remain identical. Furthermore, from a simulation conducted over 100 time steps it can be seen that Case 2 produces 7 percentage points more DP outcomes (44.4 % vs. 37.0 %) than Case 1 under uniform input distributions.

5. Evaluation

From the evaluation conducted, out of 54 possible scenario combinations, Case 1 (physical damage only) yields 34 P and 20 DP, whereas Case 2 (including psychological harm) yields 30 P and 24 DP. This is visualized in Figure 1 in the 7.4% drop in proportional outcomes when psychological harm is accounted for.

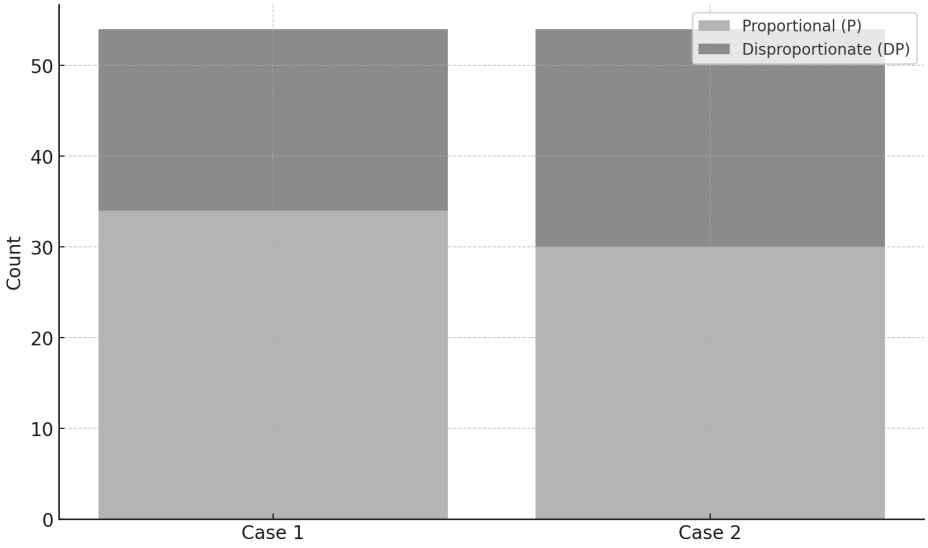

Figure 1: Evaluation for both cases

To observe how judgments accumulate over successive engagements, two discrete time stock and flow stocks are implemented: Cumulative P and Cumulative DP with flows driven by the instantaneous PA decision each step. Under uniform scenario sampling, the time series shown in Figure 2 lets seeing that Case 1's cumulative P stock rising approximately linearly to ~34 by step 54, then plateauing, while Case 2 grows more slowly, plateauing around 30 by the same step. This divergence illustrates how Case 2's inclusion of psychological damage systematically reduces the rate at which proportional judgments accrue.

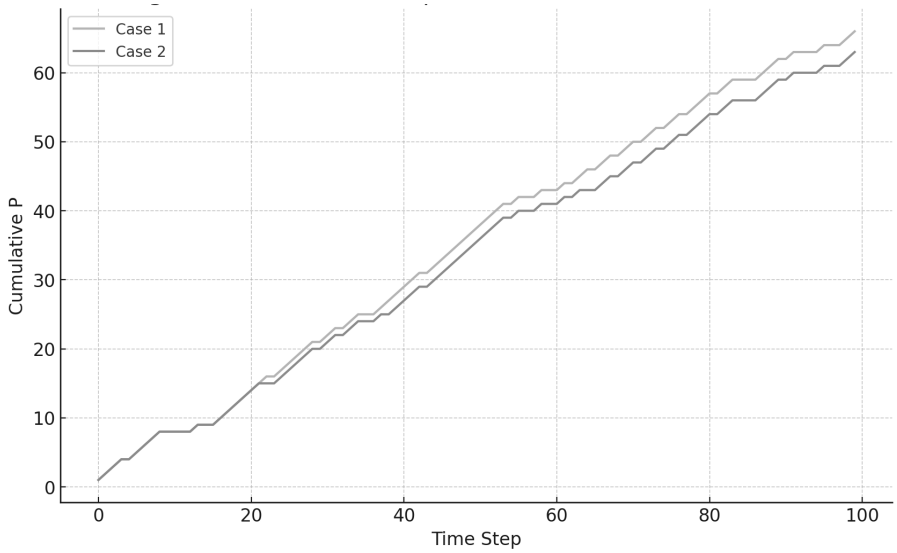

Figure 2: Cumulative proportionality assessments over time

Further, one's input probability is varied at a time (high-severity injury, high-severity death, and object damage likelihood) from 0 % to 100 %, holding other inputs uniform. To this end, Figure 3 plots the proportion of P judgments versus the probability of "High" injury: Case 1 declines from ~80 % to ~20 %, while Case 2 starts ~75 % and falls more steeply to ~15 %. Similar curves for death severity and object damage (not shown) confirm that psychological considerations amplify sensitivity, especially to object damage, shifting the curves downward by 3–5 percentage points on average.

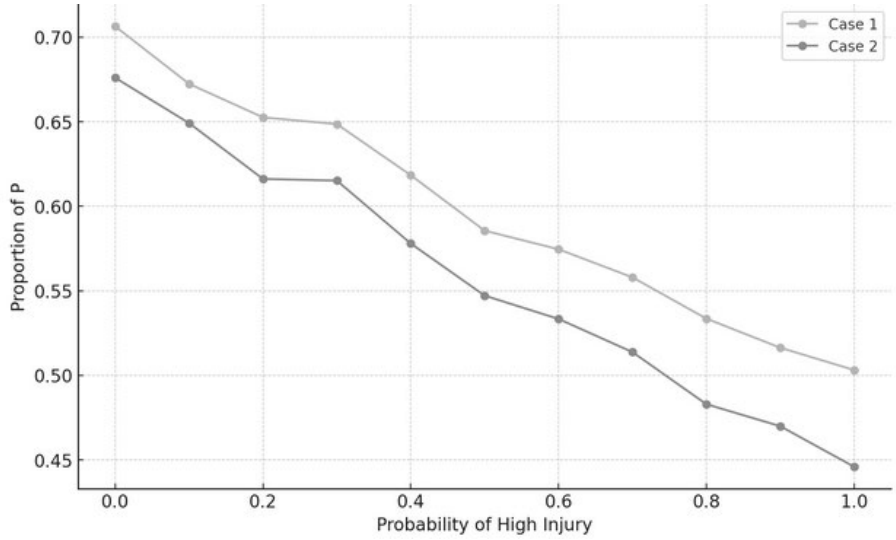

Figure 3: Sensitivity analysis to high injury

To explore interactions, a two-way are swept over p_H_injury and p_H_death, computing the difference in P proportions (Case 1 – Case 2) at each grid point. The resulting heatmap (Figure 4) reveals that the largest deltas (~5 pp) occur when both injury and death probabilities are high, indicating regions where psychological harm most strongly drives conservative (DP) outcomes. Moreover, from statistical two-proportion z-tests at each cell show that nearly 48 % of the grid cells exhibit a significant difference ($p < 0.05$), underscoring the robustness of this effect.

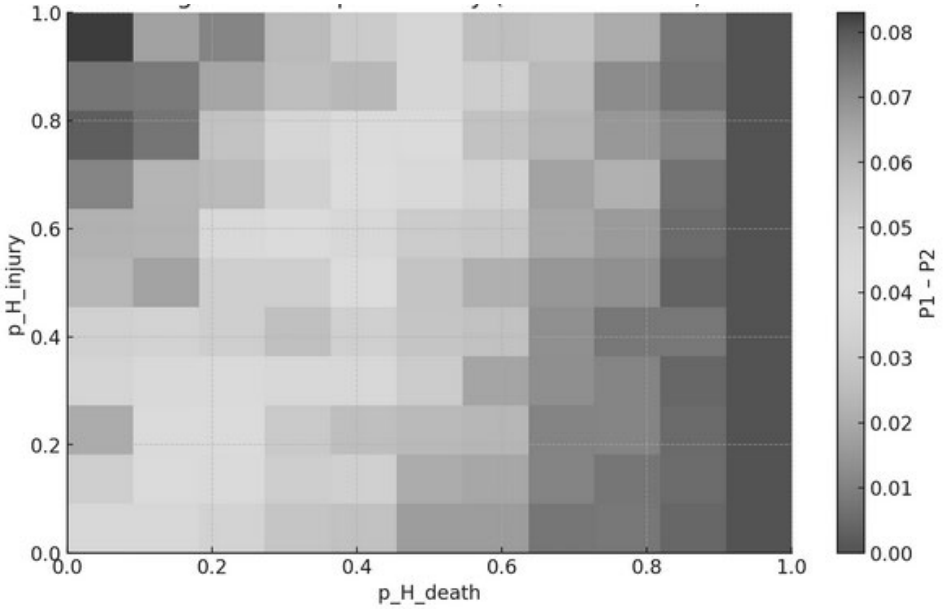

Figure 4: Delta Proportionality (Case1 and Case 2)

Aggregating across all parameter sweeps, the mean difference in proportional judgments between Case 1 and Case 2 is ~3.1 percentage points, with a one-sample t-test strongly rejecting the null of zero difference ($t \approx 16.1$, $p \ll 10^{-30}$). Such statistically significant disparities, coupled with the systematic slowing of P accumulation and heightened sensitivity to collateral-damage inputs, highlight how incorporating psychological harm leads to more conservative proportionality assessments. These findings validate the SD model's utility in "what-if" exploration and reinforce the operational importance of non-physical harm in rules-of-engagement design.

Hence, transitioning from Case 1 (physical injury only) to Case 2 (physical + psychological injury) systematically shifts the proportionality profile toward more conservative judgments: the baseline count of proportional rulings falls by 7 percentage points, cumulative proportional assessments are made more slowly, and sensitivity curves to high-severity injury, death, and object damage uniformly lie below their Case 1 counterparts by 3-5 pp. Two-way parameter sweeps reveal the largest $\Delta P = P_1 - P_2$ (up to ~8 pp) when both injury and death probabilities are high, with nearly half of all grid cells exhibiting statistically significant differences ($p < 0.05$). Thus, incorporating psychological harm in the collateral damage component of the proportionality assessment not only increases the overall frequency of disproportionate outcomes, but also amplifies the model's responsiveness to variations in collateral-damage parameters, underscoring the critical role of non-physical suffering/harm in shaping robust, precautionary proportionality assessments.

6. Conclusions

In this research, a SD model for proportionality assessment in military operations was developed, evaluated, and proposed.. By encoding 54 collateral-damage scenarios into instantaneous proportionality assessment outcomes (P vs. DP), then aggregating these through cumulative stocks, this research demonstrates how the inclusion of psychological harm (Case 2) consistently reduces proportional rulings by roughly 7 percentage points, slows the accumulation of proportional judgments, and amplifies sensitivity to key input parameters. One-way and two-way sensitivity sweeps, coupled with statistical hypothesis tests, confirmed the robustness of these effects across a broad parameter space, while time-series and heatmap visualizations provided intuitive insights into the dynamic behaviour of this model. Together, these results reflect the model's utility as both an analytic lens on doctrinal trade-offs and a decision-support tool for military targeting decision-making support.

As future research perspectives, several paths are seen for extending this framework. First, introducing endogenous feedback, where rising Cumulative DP levels dynamically adjust future military advantage thresholds, approach that would capture adaptive policy resistance and command learning. Second, by integrating or extending this model with complementary methods (e.g., agent-based or cellular automata modules) could reveal how spatial heterogeneity and local interactions alter aggregate outcomes. Third, by considering calibration against historical engagement data and expert judgment elicitation exercises that

would strengthen real-world validity. And fourthly, by expanding the collateral-damage taxonomy (e.g., including economic or cultural loss metrics), coupling with live operational data feeds, and embedding the model within interactive C2 dashboards could contribute to bringing this model toward operationalizing proportionality assessment in multi-domain operations settings.

Deepfake Technology in Social Engineering: Threats, Detection and Defence Strategies

Tanaka Makamure and Daniel Ogwok
University of Johannesburg, South Africa

222060509@student.uj.ac.za
danielo@uj.ac.za

Abstract: Big developments in the field of Artificial Intelligence (AI) have significantly improved deepfake technology, allowing individuals to create realistic synthetic media. As a result, deepfakes have become a very effective tool for social engineers by allowing them to accurately impersonate colleagues and authority figures to gain the trust of individuals and manipulate them. High-profile cases such as the Arup scam and the UAE fraud case highlight how attackers are leveraging these techniques in real-world scenarios and the devastating financial consequences they bring. In response, several technical detection tools have been developed, many of which rely on deep learning techniques. However, these should not be used in isolation. An effective defence strategy requires organisations to supplement these technological tools with other strategies, such as employee training, awareness campaigns and secure security policies. This creates layers of security, capable of mitigating risks posed by deepfake social engineering.

Keywords: Deepfakes, Social engineering, Exploits, Cybersecurity threats, Generative adversarial networks, Synthetic media

1. Introduction

Advancements in Artificial Intelligence have led to the creation of realistic synthetic media known as deepfakes (Pedersen, et al., 2025). Techniques such as generative adversarial networks (GANs) have enabled deepfake technology to convincingly replicate faces, voices and behaviours, making it very difficult for an individual to distinguish synthetic from authentic media (Yang, et al. 2021). Although such technology can be useful in fields such as entertainment, it can also be used maliciously, particularly in social engineering exploits.

Social engineering, unlike other cyber security exploits, focuses on the exploitation of human vulnerabilities, rather than technical weaknesses, to deceive and manipulate people into revealing private and confidential information (Siddiqi, Pak, & Siddiqi, 2022). Traditional social engineering attacks, such as phishing, rely on gaining human trust to be successful. The integration of deepfake technology into such attacks has the potential of aiding in the acquisition of this human trust, making social engineering attacks more effective.

The convergence of deepfake technology and social engineering presents a concerning threat to cybersecurity. This paper aims to explore how deepfakes have made it easier to manipulate and deceive people, enhancing the effectiveness of social engineering exploits. Furthermore, it reviews the current strategies being employed to detect and defend against such attacks. By taking into consideration the current state of knowledge, this paper also seeks to uncover the challenges that remain in protecting organisations against deepfake-based attacks. The research question being addressed therefore is "How is deepfake technology being used in social engineering attacks, and what strategies exist to detect and defend against them?"

The rest of the paper is structured as follows: Section 2 gives background information on the generation of deepfake media and provides an overview of social engineering tactics. Having explored these key concepts, Section 3 then discusses some case studies where deepfake technology was successfully used to launch social engineering attacks, paying attention to the attack mechanisms used. Section 4 then focuses on the detection tools that are currently being used, from tradition to deep-learning based ones. Finally, Section 5 explores the additional measures that organizations should have in place to complement technical detection strategies and provides a recommendation strategy for companies in the battle against these attacks.

2. Background

Although the introduction has outlined the growing threat presented by deepfakes in social engineering, it is important to understand the background information of these concepts. By first understanding the different types of deepfakes along with how they are generated, and what makes social engineering attacks effective, the convergence between the two fields becomes clearer. This section therefore provides an overview on deepfake technology, social engineering, and the intersection between them.

2.1 Deepfake Generation

The increasing access to cell phones, the availability of digital media on social media platforms, and advances in the field of machine learning have allowed for the manipulation of pictures, videos, and audio files to generate synthetic but realistic media, referred to as deepfakes (Masood, et al., 2022). The generation of the altered multimedia is done by machine learning algorithms, mainly GANs. Deepfakes fall under two classes, namely visual and audio deepfakes. Visual deepfakes can be classified into four categories namely attribute manipulation, identity swap, entire face synthesis and face reenactment (Akhtar, 2023). Attribute manipulation focuses on altering some facial features from authentic media, producing deepfakes with edited faces. Identity swap, on the other hand, involves the replacement of a person's face in the original video, with a different face, giving the illusion that the other person was in the video. Entire face synthesis involves using GANs to create new face images and placing them in an original video. Face reenactment is the process of replacing the facial expression of individuals in an original video with those of other individuals (Akhtar, 2023). Audio deepfakes are grouped into two categories namely, text to speech (TTS) where a speech is generated using someone else's voice, and voice conversion (VC) which involves the conversion of a speaker's voice to sound like someone else, without changing the words being said (Dagar & Vishwakarma, 2022). Deepfakes have become so sophisticated, with studies indicating that both humans and machine learning algorithms struggle to consistently distinguish them from authentic media (Korshunov & Marcel, 2018).

2.2 Social Engineering

Social engineering attacks occur when cybercriminals manipulate individuals into revealing confidential information or trick them into giving them access to a system (Hijji & Alam, 2021). Therefore, instead of attempting to circumvent firewalls and intrusion detection systems, social engineering exploits human vulnerabilities through techniques such as deception or manipulation to breach security (Wang, Zhu, & Sun, 2021). Such attacks are often successful as studies have shown human beings to be the weakest links when it comes to cybersecurity (Hijji & Alam, 2021). A common social engineering attack is phishing, where an attacker sends a message that is seemingly legitimate, prompting users to follow instructions detailed in the message. One way of conducting a phishing attack is through voice communication, where an attacker tricks users into providing sensitive information via a phone call. This is also known as vishing (Syafitri, et al. 2022). Most social engineering attacks involve an attacker gaining the trust of an unsuspecting user by posing as a legitimate entity.

2.3 Intersection Between Deepfakes and Social Engineering

The intersection between deepfake technology and social engineering has brought about a new class of cyber threats. Instead of just relying on text-based impersonation for social engineering attacks, hackers can now leverage seemingly legitimate audio and video media to gain the trust of unsuspecting users (Ferrara, 2019). Any form of social engineering attack that makes use of video or audio media, such as vishing, can be enhanced by deepfake technology. An example could be the use of deepfake technology to impersonate a manager asking an employee to transfer money into his account, or to provide some confidential information (Westerlund, 2019). This fusion increases the chances of success for attackers as many traditional defence mechanisms often struggle with recognising synthetic fabricated media (Martinek & Bartuzi-Trokielewicz, 2025).

Deepfake technology provides several tools that significantly enhance the strength of social engineering tactics. An example would be the use of voice cloning in vishing and impersonation attacks. These manipulation attacks are heavily dependent on the attacker's ability to pose as a trusted figure and gain the victim's trust. Deepfakes enhance this through the voice synthesis functionality, allowing attackers to convincingly mimic colleagues or executives over the phone. Compared to traditional vishing, where scammers' accents often raise suspicion, audio deepfake technology can mimic accents with high accuracy, reducing the victim's ability to identify the scam (Pedersen, et al., 2025).

Furthermore, combining audio and video deepfake techniques has the advantage of making the manipulated content look more authentic. This could happen when fraudsters use real-time video manipulation tools together with audio synthesis to create a realistic video of the figure being impersonated. A common example would be the use of this combination in video meetings, effectively tricking the victim into believing that they are interacting with their colleague or boss (Muhly, Chizzonic, & Leo, 2025). This amplified attack can be very successful if organisations rely only on visual confirmation to verify requests. To structure the analysis of this

intersection, this paper proposes a taxonomy mapping deepfake method, social engineering technique and corresponding defence strategy, presented in full in Section 5.3.

3. Deepfakes in Social Engineering Attacks

To better understand the application of deepfake technology to enhance social engineering, it is useful to examine real-life case studies where synthetic media was utilised in cyberattacks. These case studies showcase the mechanisms discussed in the previous section in real-world scenarios, demonstrating their effectiveness and the devastating impacts they leave on the victim organisations.

3.1 Arup Deepfake Video Scam

One of the most impactful cases of deepfakes being used in social engineering occurred in 2024 when an employee working at Arup, a UK-based company, was scammed into transferring money to the attackers (Lin, 2025). The attack started with a phishing email, where the chief financial officer (CFO) requested transfer of funds. The employee's doubts were wiped when the attackers made use of deepfake technology to impersonate the CFO and other company employees, cloning their faces and voices. This managed to convince the employee that the communication was legitimate, and he proceeded to transfer funds to five different Hong Kong bank accounts (Lin L. S., 2025). In total, this social engineering attack resulted in a financial loss of approximately US$25.6 million (Doraisamy, et al. 2025). This attack demonstrates the dangerous outcomes of bringing together deepfakes and manipulation techniques, in this case, the use of audio and video deepfakes to convince an unsuspecting individual to comply with an urgent request.

3.2 UK Energy Company Scam

A similar attack occurred at a UK-based energy company, where attackers leveraged voice cloning technology to impersonate one of the company's executive official (Farid, 2025). The attack began when a phone call was made to the company's CEO from an individual who was impersonating his superior. Initially, the CEO had no reason to doubt the call, as the deepfake voice cloning convincingly replicated the superior's voice as well as his German accent (Pedersen, et al., 2025). Believing this call to be genuine, the CEO was tricked into authorising a payment transfer of approximately US$ 243,000 to a Hungarian supplier. The attackers subsequently requested additional funds, but the CEO grew suspicious after noticing no reimbursements had been made. Investigations carried out of the case concluded that the attackers had used a commercially available voice-generating software to impersonate the superior (de Rancourt-Raymond & Smaili, 2022). This case is an example of how voice cloning on its own is powerful enough to catch individuals off-guard and exploit their trust, manipulating them into doing what exactly the attacker wants.

3.3 UAE Bank Scam

A third high-profile deepfake social engineering attack occurred in 2020 at a United Arab Emirates (UAE) bank. To execute this attack, cybercriminals used voice cloning technology to mimic the voice of a company's director and proceeded to make a call to a bank branch manager asking him to authorise a series of transfers (Farid, 2025). This request for funds was accompanied by emails and supplementary documents from an alleged lawyer, adding credibility to the request. Since the branch manager was familiar with the director's voice, and was additionally reassured by the supporting documents, he had no reason to suspect foul play, therefore he proceeded with approving the transactions (Lin L. S., 2025). In total, approximately US$35 million was transferred to the attackers through various international accounts, and a portion of it was traced to the United States. Investigators who were assigned to this case concluded that the attackers had used speech samples from public sources or hijacked communications to clone the director's voice. This case is regarded as one of the biggest financial fraud attacks utilising deepfake technology (Lin L. S., 2025). This social engineering attack demonstrates how traditional phishing methods such as email attacks are significantly enhanced using deepfakes, making the process of gaining human trust, and ultimately manipulating them much easier.

3.4 Almost Successful Financial Scams

Not all attempts to use deepfakes in social engineering have been successful, but they still demonstrate the harmful potential this convergence possesses. In 2020, the advertising company WPP became the target of a deepfake scam, where attackers leveraged deepfake audio cloning to impersonate the CEO (Zhang, et al. 2025). The attack was initiated when the fraudsters used a public image of the CEO to create a WhatsApp account and proceeded to arrange a virtual meeting with a senior executive. They then made use of the CEO's voice and a public footage to impersonate the CEO during the meeting, and they requested for a funds transfer (Muhly, Chizzonic, & Leo, 2025). A similar attack targeted a Swiss financial institution in 2024, where

cybercriminals used deepfakes to mimic the company's chief financial officer (CFO). However, the financial clerk managed to recognise inconsistencies in the fake CFO behaviour and dress code, making the attack unsuccessful (Muhly, Chizzonic, & Leo, 2025). While both scam attempts were unsuccessful and no money was transferred, it highlights how audio and video deepfake technology can be combined, to reinforce trust and credibility.

4. Deepfake Detection

The case studies discussed in the previous section demonstrate how deepfake technology can be applied to boost the success of social engineering attacks, resulting in severe financial consequences. From this information, it becomes apparent that this convergence presents a real threat, and therefore there is need for countermeasures to detect and protect organisations against such attacks. This section examines the current technology being used by detection tools in the battle against deepfakes, with the aim of evaluating their effectiveness and highlighting the limitations that need to be addressed in defending against these amplified attacks.

4.1 Audio Deepfake Detection

Multiple approaches to audio deepfake detection have been explored over the years. One such approach involves the extraction of features from an audio file, then applying machine learning algorithms to detect whether the voice has been tampered with (Stroebel, et al. 2023). The use of algorithms such as GMM (Gaussian Mixture Model) and LCNN has been proposed for such detections. The findings indicate that these models perform well on fully synthesised audio files, however, they tend to struggle with partially synthesised ones.

A more effective approach uses deep learning algorithms, such as neural networks, to learn patterns that emerge in fabricated audio files, and use those patterns in classification (Shaaban, Yildirim, & Alguttar, 2023). This can be achieved using CNNs to analyse features from audio mel spectrograms, which can be used to differentiate altered audio files from genuine ones (Stroebel, et al. 2023). Several experiments have shown that the CNN-based models outperformed traditional GMM-based ones in distinguishing spoofed audio files from authentic files. For example, an analysis carried out on the ASVspoof2019 dataset revealed that CNN models achieved a lower Error Equal Rate (ERR) of 0.59 compared to 6.4 achieved by GMM models. The lower ERR indicates the superiority of CNN models in detection accuracy (Salih, et al., 2025). However, even though these models perform well in a controlled environment, they often struggle with generalisation, limiting their overall effectiveness in real world situations.

Table 1: Comparison of audio deepfake detection methods

Method	Strengths	Weaknesses
GMM/LCNN	Strong on fully synthesised audios	Performance drops on partial audio
CNN + mel spectrograms	Better performance than GMM/LCNN	Poor generalisation

4.2 Traditional Image Deepfake Detection Methods

Traditional deepfake detection tools, such as Error Level Analysis (ELA), rely on looking for unnatural facial movements, or imperfections within the fabricated videos such as speech consistencies, shadows as well as lack of breathing (Taeb & Chi, 2022). If such a tool detects one or more of these inconsistencies, that video will be flagged as fabricated. However, the introduction of AI algorithms such as convolutional neural networks (CNNs) and GANs has significantly improved the quality of deep-fakes, eliminating these imperfections. Therefore, these traditional tools are becoming ineffective, particularly against deep learning based deepfakes (Taeb & Chi, 2022).

4.3 Deep Learning-based Detection

A better approach to deepfake detection is to utilise deep learning algorithms such as CNNs and deep neural networks (DNNs) (Stroebel, et al. 2023). These deep learning techniques are classified into two categories namely holistic and feature-based categories.

Holistic approaches to deepfake detection, such as support vector machines (SVM) and CNN classifiers, focus on the entire face, to detect irregularities that can be used to differentiate authentic images from fabricated ones (Taeb & Chi, 2022). An experiment carried out by (Mallet, et al., 2023) demonstrated the effectiveness of a CNN model in identifying synthetic images, achieving a detection accuracy of 88.33% on a dataset of real and

fake faces. However, despite this good performance, holistic approaches face generalisation challenges. An analysis by (Raza, et al., 2026) has shown that CNN-based models suffer a performance decline of about 15% when evaluated on different datasets. This suggests that even though holistic approaches show promising results in controlled environments, their effectiveness in real-world situations is limited.

Feature-based methods, on the other hand, extract features that are unique to deepfakes, and these are then used to classify real and fabricated media. These features are grouped into biometric, media and model classes. Biometric features are human features, such as eye and lip movement, head pose and eyebrows, that can be used in the distinction of deepfake and genuine videos. Media features focus on information like noise and inconsistencies between frames in media, and this information can be used to identify videos that have been tampered with (Zhang, et al. 2025). Model features, unlike media features, are based on the model used in the deepfake generation and refer to specific fingerprints left behind by the models, particularly GAN models, in the generated media. Deep learning models can scan for the presence of these fingerprints to help in the identification of fake media (Zhang, et al. 2025) (Taeb & Chi, 2022). However, the weakness of fingerprint detection stems from the fact that models trained to detect GAN-based deepfakes struggle with diffusion-based deepfakes, because these introduce entirely different artifact patterns (Singh & Dhumane, 2025).

Table 2: Comparison of deep learning-based detection approaches

Approach	How it works	Strengths	Weaknesses
Holistic (SVM and CNN)	Full face analysis	High detection accuracy on known dataset	Poor generalization
Feature-based (Biometric, media and model)	Extracts deepfake-specific features media	Captures movement inconsistences	Struggle with diffusion-based deepfakes.

4.4 Limitations

Although the above-mentioned detection methods show promising results, they face several limitations. Experiments on both machine learning and deep learning models have revealed that these detection methods struggle to generalise. Therefore, while they perform well on a single dataset, the detection accuracy drops when the models are evaluated on unseen deepfakes. An experiment by (Singh & Dhumane, 2025) has highlighted this performance drop, where a CNN-based model that achieved detection accuracy of 90% on one dataset only managed a 60% accuracy on a new unseen dataset.

Another significant limitation of existing detection tools is that of scalability. State-of-the-art detection models require significant computing resources including premium GPUs and large memory capacity (Singh & Dhumane, 2025). As a result, real-time deepfake detection remains a challenge, especially for smaller organisations, with limited computer infrastructure.

Finally, there is a limitation of partial media manipulation. As discussed in Section 4.1, GMM and LCNN based classifiers produce good performance on fully synthesised audio, however, their performance drops when evaluating partially synthesised samples (Stroebel, et al., 2023). This suggests that attacks that blend authentic and spoofed media have a higher chance of evading detection. Table 3 presents a summary of limitations faced by each detection approach.

Table 3: Summary of limitations across detection approaches

Detection approach	Limitations
Traditional image detection methods (ELA)	Obsolete against CNN-generated deepfakes
GMM and LCNN (audio detection)	Poor performance on partial media
Audio CNN + mel spectrogram	Poor generalisation
Holistic (CNN and SVM)	Performance drop across datasets (15% drop)
Feature-based approach	Struggle against diffusion-based deepfakes Computationally heavy

Overall, these limitations highlight that no single detection method offers complete protection against deepfake-powered social engineering.

5. Defence Strategies

While the detection tools discussed in the previous section provide a layer of defence against deepfakes, they do not always flag every manipulation attempt. Therefore, detection tools on their own cannot fully mitigate the threats possessed by deepfake social engineering exploits. Consequently, organisations should have other defence mechanisms in place to reduce the probability of successful attacks. This section discusses human-centric strategies along with organisational safeguards that can be utilised in shielding companies from these attacks. It then concludes by suggesting a recommended strategy organisations can employ, by structuring their defence in layers, adopting a defence-in-depth approach to security.

5.1 Human-centric Strategies

Humans have been identified as the weakest link when it comes to cybersecurity (Hijji & Alam, 2021), therefore, in addition to having automated detection tools, it is also necessary to ensure that employees are made aware of the threat posed by deepfake technology. One way of achieving this is by organizing training and awareness campaigns focused on equipping individuals with the knowledge required to detect altered media (Lin L. S., 2025). A study conducted in Bangladesh demonstrates the effectiveness of awareness campaigns in the battle against deepfakes. This study was conducted in two phases, with the results from phase one indicating that 65% of the sample group was totally unaware of deepfakes. However, after being made aware of this concept, phase two results were promising, with 70% of the group feeling confident that their deepfake detection abilities had improved (Ahmed, et al. 2021).

5.2 Organisational Safeguards

Organisations can also take a proactive approach in the battle against deepfake scams by putting in place controls and safeguards to assist in the detection and defence against attacks. By defining strong and secure policies, companies ensure that employees have an established framework to follow when dealing with requests (Muhly, Chizzonic, & Leo, 2025). A practical example would be having a policy outlining secure communication tools and platforms organisational employees should use, that way, any request made from a non-approved platform is immediately shot down (Pedersen, et al., 2025). Furthermore, organisations should outline reporting procedures to follow when employees face deepfake scams (Pedersen, et al., 2025).

5.3 Recommended Approach

Given the complexity of deepfake-fuelled social engineering attacks, having a single mitigation strategy cannot guarantee complete protection. Case studies discussed in section 3 demonstrate that attackers use different deepfake methods and social engineering techniques, each requiring a unique response. This paper therefore proposes a taxonomy that maps the attack method and social engineering technique to the appropriate defence strategy.

Table 4: Taxonomy of Deepfake Social Engineering Attacks and Defences

Deepfake method	Social Engineering technique	Real-world example	Defence strategy
Audio only	Vishing	UK energy and UAE bank scams	CNN mel spectrogram analysis. Call verification policy. Employee training.
Video and Audio	Visual and audio impersonation	Arup scam, WPP attempt	Holistic CNN. Feature-based analysis. Secure communication policies.
Audio and Documents	Phishing enhancements	UAE bank scam	Email filtering. Audio deepfake detection. Multi-channel verification policies.

As the table illustrates, organisations should adopt a defence-in-depth strategy, combining technical detection tools, human awareness and training, along with secure organisational policies. For example, a vishing attack

requires a combination of audio CNN detection and strict call verification policies, ensuring that even if the detection tool fails, a trained employee following the policy acts as a secondary defence. The key

advantage of this multi-layer approach to security is that even if one layer is bypassed, such as an employee being tricked, the organisation will have additional safeguards, preventing a single point of failure.

6. Conclusion

Deepfake technology has been significantly enhanced by breakthroughs in the field of artificial intelligence, enabling the creation of convincing and realistic synthetic audio and video media. This enhancement has negatively revolutionised deepfake social engineering attacks, allowing cybercriminals to exploit individual trust with ease, putting organisations at risk of deepfake fraud. This paper introduced key concepts in the fields of deepfakes and social engineering by exploring the different ways in which deepfakes are created and introducing the key factors that allow social engineering exploits to be successful. Then it proceeded to examine how the two fields can be brought together, describing how deepfake technology can be utilised in social engineering attacks such as vishing and video conference scams, by impersonating an authoritative figure. Several high-profile case studies were additionally explored, further reinforcing the intersection of the two fields and the devastating consequences it has on the victims. The discussion then shifted to the possible solutions by examining the current detection tools that are available, ranging from early forensic tools to deep-learning based approaches. Additionally, the paper considered necessary supplementary defence mechanisms, such as training and awareness campaigns for employees and secure organisational policies, which can be used in conjunction with technical detection tools, effectively implementing a defence-in-depth approach to securing organisations. Finally, this paper proposes a taxonomy mapping attack methods to the appropriate defence strategies, offering a practical framework for organisations.

The objective of this paper was to investigate the role of deepfake technology in social engineering by discussing the risks posed and the detection and defence measures that can be employed. This objective has been met through case study explorations and a thorough examination of the current state of detection and defence mechanisms. Although total mitigation of this threat remains a challenge due to huge leaps in the field of AI, this paper identifies a layered approach to security as the best course of action against deepfake social engineering.

Detecting DDoS Attacks in IoT Healthcare

Eurydice Tracy Makena and Sara Sutton
Grand Valley State University, Allendale, MI, USA

makenae@mail.gvsu.edu
suttosar@gvsu.edu

Abstract: The increased adoption of IoT devices in healthcare domains has significantly increased the attack surface, leaving critical infrastructure vulnerable to attacks such as Distributed Denial of Service (DDoS). Our work investigates the role of feature selection and temporal dependency modelling in detecting MQTT (Message Queuing Telemetry Transport) DDoS attacks using the CICIoMT 2024 dataset. We compare two approaches; using the Naïve Bayes model which assumes flow independence and Long Short-Term Memory (LSTM) model, which captures sequential dependencies in the raw network flows. Feature selection was also performed to reduce 84 raw features to 31 informative features. Our preliminary results show that the LSTM model outperformed naïve bayes by leveraging the temporal patterns that are characteristic of DDoS traffic. This study evaluates the importance of guided feature selection and temporal dependency modelling in DDoS detection in IoT healthcare networks.

Keywords: DDoS detection, IoT healthcare, MQTT, Long short-term memory (LSTM), Intrusion detection

1. Introduction

Internet of Things (IoT) devices continue to be widely adopted across various domains, and it is predicted to rise to over 40 billion devices by 2030. One such domain is in healthcare where IoT devices such as patient monitors, infusion pumps, and wearables interact to enable real-time healthcare delivery. With this adoption comes a wide range of cybersecurity challenges as discussed by (ElSayed et al., 2025) in their paper. This connectivity introduces critical security risk, IoMT devices often run outdated firmware, use weak authentication mechanisms, and run on limited computational resources making it challenging to implement security measures. This makes them easy targets for botnet recruitment and large-scale DDoS attacks that bring down organizations. (Censinet.com, 2026) estimated that the cost of downtime from DDoS attacks is over $100,000 per hour. Service interruptions in healthcare environments directly impact patient safety. Therefore, robust defences must be prioritized to ensure continuity of services.

Among the protocols commonly exploited in IoMT environments, MQTT (Message Queuing Telemetry Transport) is particularly vulnerable due to its lightweight publish/subscribe model, weak authentication mechanisms, and unencrypted message transmission. Attackers exploit MQTT through Connect and Publish Flood attacks that overwhelm brokers and clients with excessive traffic, overwhelming legitimate device communications. In their paper, (Lakshminarayana et al., 2025) evaluated the security vulnerabilities of MQTT v5.0 protocol that made them susceptible to attacks. They found that the protocol's support for large, unbounded properties such as connect properties and user-defined metadata enables attackers to craft oversized or numerous malicious packets that exhaust broker resources like CPU and memory.

Most traditional intrusion detection methods are signature based and rely on static rules to flag suspicious activities. However, as attacks become more sophisticated, these methods struggle to detect varying attack patterns. While machine learning has also advanced beyond signature-based detection, existing methods mostly treat the network flows as independent events and fail to capture the temporal relationships between the flow attributes. Our work addresses two fundamental research questions in DDoS detection, are there specific features that most effectively discriminate between benign and attack traffic and does modelling short-term flow sequences provide quantifiable benefits over independent flow classification in detecting MQTT-based DDoS attacks. To address these questions, we make the following contributions: We perform feature selection through Random Forest importance scoring and Information Gain to identify a smaller, informative feature subset. We then evaluate two contrasting models, the Naive Bayes classifier, which treats each flow independently; and an LSTM model, which captures temporal dependencies across consecutive flows. We demonstrate that temporal modelling achieves better results in detection accuracy and false positive reduction on the MQTT Connect and Publish Flood traffic from the CiCIoMT 2024 dataset.

2. Related Works

With the rise of cyberattacks on IoMT devices, such as DDoS, researchers have made efforts to develop detection algorithms and mitigation techniques.

(Clark et al., 2024) leveraged machine learning models for anomaly detection to identify abnormal activity in IoMT systems with a goal of detecting DoS and ARP spoofing attacks. Their research focuses on Bluetooth, Wi-Fi, and MQTT enabled devices where they trained different supervised and unsupervised machine learning models to classify network traffic as either malicious or benign. The models were trained on the CIC IoMT 2024 dataset, and the findings were that the decision tree model performed best for detecting DoS attacks on Bluetooth devices, while the random forest model performed best for detecting ARP spoofing attacks on Wi-Fi and MQTT enabled devices.

(Hnamte et al., 2022) implemented a Naïve Bayes classifier for DDoS detection in IoT networks. They selected and optimized features using statistical techniques, specifically the correlation coefficient and Dice similarity coefficient. A Naïve bayes classifier was trained to accurately distinguish between malicious and benign traffic while reducing false positives. Their model achieved a high accuracy of 89.7% and true positive rates of about 90%.

(Kirubavathi et al., 2024) proposed a two-model based approach to anomaly detection trained on the CICIoMT 2024 dataset. The models used were Autoencoder for identifying errors through reconstruction errors and TabNet for utilizing attention mechanisms on tabular data. The Autoencoder had an input layer and an output layer of the same shape that attempted to reconstruct the traffic. If the resultant error was beyond a predetermined threshold, then it implied that some unusual activity was occurring. The TabNet used attention mechanisms to identify anomalies from the output of the model.

(Berguiga et al., 2025) presented a hybrid deep learning intrusion detection system for IoMT devices. The methodology combined two neural network architectures; Convolutional Neural Network (CNN) and Long Short-Term Memory (LSTM) neural network trained on the IoTID20 and the Edge-IoTset datasets. The datasets contain samples categorized into different attacks, including DoS and DDoS attacks. The CNN model performed feature extraction on the data while the LSTM model was used for sequence data prediction. The hybrid model achieved a high accuracy of 99.92%.

(Zabeehullah et al., 2025) also suggested a hybrid CNN-LTSM model for DDoS detection in IoMT. They used the CNN model for spatial feature extraction, and the LTSM module was trained on time-series data for network traffic features, augmenting their pipeline with SHAP-based explainability. They used the CICDDoS2019 and IoT Healthcare Security datasets, achieving a high accuracy of 99.59%, and providing interpretable feature attributions.

(Bhutia et al., 2022) proposed a three-phase methodology using just three machine learning algorithms: the KNN classifier, the Logistic Regression classifier, and SVM (Linear and RBF), for DDoS detection at the source, which is often bots. Their dataset of choice was traffic data collected from various commercial IoT devices that were exploited in the MIRAI and BASHLITE DDoS attacks. They extracted 23 features for classification of traffic as either benign or junk, and their proposed models achieve a detection accuracy of 99%.

(Phan et al., 2024), feature selection techniques of IoT attacks (Information Gain, Recursive Feature Elimination, Random Forest, XGBoost, and Logistic Regression) for machine learning detection on the CIC IoT 2023 dataset. Their results established that Random Forest and Information Gain consistently achieved high and stable accuracy, supporting our decision to use the two methods for our feature selection.

Prior works have advanced feature engineering and machine learning methods for IoMT DDoS detection. While hybrid models combine spatial and temporal learning, our work isolates and investigates the contribution of temporal learning by comparing a probabilistic classifier with a temporal sequence model using the same selected feature set.

3. Design And Methodology

3.1 Dataset

We use the CiCIoMT 2024 dataset (Dadkhah et al., 2024), generated by the Canadian Institute of Cybersecurity by executing different cyberattacks against an IoMT testbed of 40 devices across multiple protocols. Overall, the dataset consists of attacks categorized into different attacks such as DDoS, DoS, Recon, MQTT, and spoofing. Our study focuses on MQTT DDoS traffic, specifically Connect Flood and Publish Flood variants, against benign MQTT traffic to create a binary classification problem.

The CiCFlowMeter tool is a network traffic flow generator and analyser which generates bidirectional flows. A flow consists of multiple packets that are defined by the same five-tuple (source IP, destination IP, source port,

destination port, protocol). Using the tool, we extracted bidirectional network flow statistics from the dataset PCAP files, with each flow record containing 84 statistical features characterizing packet-level behaviour including duration, packet counts, byte volumes, inter-arrival times, and flag counts.

3.2 Preprocessing and Feature Selection

To ensure consistency, non-numerical identifiers were excluded from the dataset and infinite, missing and NaN values were handled through dropping. Normalization was performed by applying MinMax scaling which converts values to a range of (0,1). CiCIoMT datasets are usually known to suffer from data imbalance, with the attack data being greater than the benign data. To address the class imbalance, we applied under sampling to the majority class during training data preparation, maintaining a balanced training distribution.

With so many features, dimensionality reduction is important to reduce the model complexity and remove noisy features that degrade model performance. Previous work by (Phan et al., 2024), compared multiple feature selection techniques for machine learning detection of IoT attacks. Their results showed high and stable performance in Random Forest and Information Gain, which we employed for feature reduction to result in a smaller, informative feature set.

Information Gain works by quantifying how much information a given feature contributes to correctly classifying an instance.$IG(D, A) = H(D) - H(D|A)$ where IG(D,A) is the information gain of a feature A on a dataset D. Features with high IG provide significant discriminative information and are prioritized for retention.

Random Forest evaluates the relative importance of each feature by evaluating how much the feature contributes to reducing the Gini impurity in the decision tree. If a feature results in a higher decrease in impurity, it is considered more important since it improves the model's ability to classify correctly.

Both methods independently ranked the 84 extracted features, and features were selected based on consistent high rankings across both methods as well as domain knowledge. Information Gain ranking showed Fwd Seg Size Min, and TCP flag counts (SYN, RST, and FIN) as the most discriminative features for distinguishing the attacks. These features reflect the handshake and connection termination patterns characteristic of MQTT Connect and Publish attacks. Other connection related features such as FWD Init Win Bytes and Bwd Header Length also ranked highly since they captured early-stage resource negotiation that would noticeably differ between benign and DDoS traffic. The Random Forest rankings corroborated these findings and where feature rankings differed significantly, domain knowledge was used to evaluate the relevance. This process resulted in a set of 31 features that effectively characterize network traffic and provide strong indicators of DDoS attacks. These include flow duration, bidirectional packet and byte counts, inter-arrival time statistics (mean, standard deviation, maximum), active and idle time metrics, header length statistics, and TCP flag counts. The selected features are summarized in Table 1.

Table 1: Selected Features

Category	Features
TCP Flag Counts	SYN Flag Count, ACK Flag Count, PSH Flag Count, RST Flag Count, FIN Flag Count
Flow-level metadata	Protocol, Flow Duration, Flow Bytes/s, Flow Packets/s, Down/Up Ratio
Packet Counts	Total Fwd Packet, Total Bwd Packets
Packet size statistics	Packet Length Min, Packet Length Mean, Packet Length Max, Packet Length Std, Packet Length Variance, Average Packet Size, Fwd Segment Size Avg, Fwd Seg Size Min
Header lengths	Fwd Header Length, Bwd Header Length
Initial Window Sizes	FWD Init Win Bytes, Bwd Init Win Bytes
Subflow bytes	Subflow Fwd Bytes, Subflow Bwd Bytes
Inter-arrival times	Fwd IAT Mean, Fwd IAT Total, Bwd IAT Mean, Bwd IAT Total, Flow IAT Mean

4. Model Architecture and Training

4.1 Model 1: Naïve Bayes

The Naïve Bayes model is a probabilistic classifier that assumes each feature contributes independently to the final decision. This assumption directly contrasts with the temporal dependency modelling of the LSTM model, making it a suitable control for assessing the contribution of sequential learning.

After the preprocessing step, each flow was represented as a vector of the selected features. We then applied a Gaussian Naïve Bayes classifier, which assumes that the feature values follow a normal distribution. During training, the model estimates the mean and variance of each feature separately for the benign and DDoS classes. For each new flow instance, the model computes the likelihood of the observed feature values under each class and assigns the class with a higher probability.

By treating each flow as an independent instance, the classification decisions were based purely on the statistical characteristics of that individual flow, without considering temporal relationships between consecutive flows.

4.2 Model 2: Long Short-Term Memory (LSTM)

Each network flow in our dataset includes a timestamp column indicating when each network activity was recorded. For temporal context, the flows were sorted chronologically based on their timestamps. Consecutive flows were then grouped into non-overlapping fixed-length sequences of 36 flows, allowing the model to observe how the traffic features evolve over short time periods rather than observing the network flows in isolation.

DDoS flooding attacks exhibit characteristic patterns of inter-arrival times and packet rates that evolve over time, whereas benign MQTT traffic tends to exhibit varying and unpredictable patterns. Since these behavioural differences evolve over time, modelling temporal order provides meaningful information for network intrusion detection.

The LSTM layer consists of 64 units feeding into a GlobalAveragePooling1D layer which aggregates the temporal representations across all timesteps. This is followed by two fully connected dense layers of 32 and 16 units respectively, each with Rectified Linear Unit (ReLU) activation and a dropout rate of 0.3. Dropout and recurrent dropout are applied to reduce overfitting. The output layer is a single dense unit with sigmoid activation for binary classification. The Adam optimizer and binary cross entropy loss function were used. The model architecture is summarized in Figure 1.

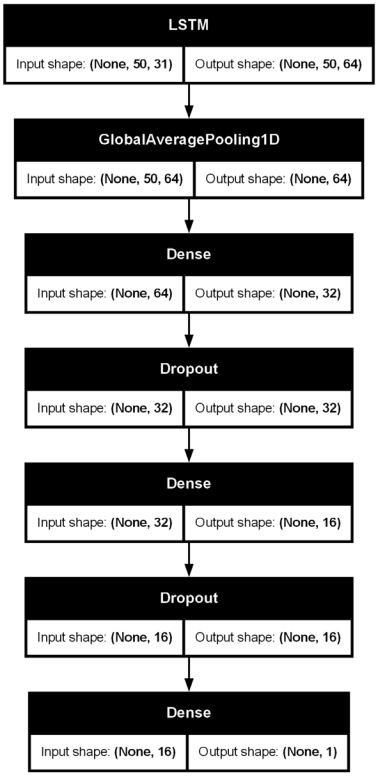

Figure 1: Model Architecture

Unlike Naïve Bayes, the LSTM retains information across timesteps, allowing it to model temporal dependencies within the flow data.

5. Experimental Results

Performance was evaluated on an unseen test set that was not used at any stage of the training process, using accuracy, precision, recall, F1-score, and the confusion matrix to assess false positive and false negative rates.

A summary comparison of the performance between the two models is shown in Table 2.

Table 2: Model Performance

Model	Accuracy	Precision		Recall		F1-Score	
		Benign	DDoS	Benign	DDoS	Benign	DDoS
Naïve Bayes	0.8990	0.99	0.86	0.69	0.99	0.82	0.92
LSTM	0.9585	0.97	0.95	0.90	0.98	0.94	0.97

Tables 3 and 4 show the normalized confusion matrices.

Table 3 Bayes Confusion Matrix

	Predicted Benign	Predicted DDoS
Actual Benign	75.3%	24.7%
Actual DDoS	0.09%	99.91%

Table 4: LSTM Confusion Matrix

	Predicted Benign	Predicted DDoS
Actual Benign	100%	0%
Actual DDoS	0.013%	99.987%

The LSTM model achieved higher overall accuracy (95.85%) compared to Naïve Bayes (89.90%). The high accuracy scores on both models demonstrate that the selected features contain sufficient discriminative information for detection. While both models demonstrated strong recall for DDoS traffic, the notable differences emerged in the benign traffic classification. The 69% score on benign traffic in Naïve Bayes indicates a high false positive rate (24.7%), where a lot of benign traffic flows were misclassified as DDoS. In contrast, LSTM improved the benign recall to 90% indicating that the temporal context helped distinguish sustained attack behaviour from legitimate short bursts of activity. In isolation, individual benign flows can resemble short attack bursts because legitimate MQTT clients frequently establish connections with brokers and publish messages in succession. This generates packet rates, TCP flag patterns and segment sizes that are similar to the early stages of a Connect or Publish attack. Without temporal context, a classifier may struggle to distinguish between a legitimate connection event and the start of a volumetric attack.

These results indicate that single flow features may not be enough to rule out false positives. The LSTM's temporal context allows it to evaluate whether a suspicious flow is part of an ongoing flood or a behavioural variation, therefore reducing false positives.

6. Conclusion and Future Works

This study examined the viability of feature selection and temporal modelling in detecting MQTT-based DDoS attacks within IoMT networks using the CICIoMT 2024 dataset. We demonstrated that guided dimensionality reduction results in concise, discriminative features that support both traditional machine learning and deep

learning classifiers. Our results show that by leveraging sequential flow dependencies, the LSTM model was able to significantly outperform the Naïve Bayes model.

Our main finding is that temporal modelling is meaningful for DDoS detection. This is because DDoS attacks usually occur as huge and repetitive volumes of normal looking traffic over short intervals of time. This is easier to distinguish from legitimate communication when modelled as sequences rather than independent instances.

Future works may include expanding beyond MQTT DDoS attacks. The CiCIoMT 2024 dataset also contains traffic data for other attack types, such as TCP SYN floods and spoofing attacks, which we did not include in our work. It would be worth exploring whether the same model trained on MQTT data can be generalised for other attacks since the network behaviour differs for each. Additionally, our current solution performs binary classification between benign and DDoS traffic. Extending this to multi-class classification to distinguish among specific attack types would provide more granular and informative detection. This would be particularly useful in critical sectors such as the healthcare industry, where accurately detecting the type of attack can inform more effective incident response efforts. Future work could also explore lightweight alternative models that could achieve comparable performance at a lower computational cost due to the resource constraints in IoMT devices. This would make deployment on constrained edge devices more feasible.

A Potential Digital Evidence Classification Model for 5G NFV Environments Using Supervised Machine Learning Algorithms

Sheunesu Makura, Lucas Blanc and Hein Venter
University of Pretoria, South Africa

makura.sm@up.ac.za
u21436135@tuks.co.za
hventer@up.ac.za

Abstract: The adoption of fifth-generation (5G) mobile networks has increased significantly due to enhanced bandwidth, reduced latency, and support for heterogeneous services. Key enabling technologies such as Network Function Virtualisation (NFV) and network slicing introduce flexibility and scalability but also expand the attack surface for cyber threats. These threats complicate digital forensic investigations, particularly the identification and classification of Potential Digital Evidence (PDE) in dynamic virtualised environments. This paper proposes a machine learning-based classification model for PDE in 5G NFV environments to support digital forensic readiness (DFR). The model integrates digital evidence collection, preservation, and storage processes with supervised machine learning algorithms to automatically classify forensic artefacts. A Random Forest classifier was evaluated using a combined dataset consisting of CIC-IDS 2017 traffic and real 5G packet captures. Experimental results demonstrate high classification performance, achieving a weighted precision of 0.97, recall of 0.93, and F1-score of 0.95. Feature importance analysis further highlights key traffic characteristics relevant to forensic investigations. The proposed model enhances forensic readiness by enabling automated identification and categorisation of relevant evidence, reducing manual effort and improving investigation timeliness in 5G NFV environments.

Keywords: 5G networks, Network function virtualisation (NFV), Machine Learning, Potential digital evidence, Digital forensic investigation

1. Introduction

Mobile networks have experienced rapid growth over the past decade, driven by increasing demand for high-speed connectivity, low latency, and support for diverse digital services (Hassan, Yau and Wu 2019). Fifth generation (5G) networks introduce advanced capabilities through technologies such as Network Function Virtualisation (NFV) and network slicing, enabling flexible and scalable network deployments (Barakabitze et al. 2020). However, these technologies also introduce new security challenges by increasing system complexity and expanding the attack surface available to cyber adversaries (Madi et al. 2021).

The dynamic and distributed nature of NFV environments further complicates digital forensic investigations, as Potential Digital Evidence (PDE), including network traffic records, system logs, configuration files, and user activity traces, may be dispersed across virtualised components with limited persistence. PDE refers to any form of digital data that may prove potentially useful to a digital forensic investigation (Gogolin 2021). Consequently, identifying, collecting, and classifying forensic artefacts in real time remains a significant challenge for investigators, particularly in highly virtualised 5G infrastructures (Makura and Venter 2024).

Digital Forensic Readiness (DFR) seeks to maximise the availability and usability of digital evidence while minimising investigation costs and response time through proactive preparation mechanisms (Tan 2001). Although prior research has proposed DFR frameworks for 5G environments, limited work has focused on the automated classification of forensic artefacts using machine learning techniques. Addressing this gap, this paper proposes a supervised machine learning-based model for classifying PDE in 5G NFV environments. The model integrates DFR processes with automated classification to support timely and accurate digital forensic investigations. A Random Forest (RF) classifier is evaluated using a hybrid dataset comprising public intrusion detection data and real 5G network traffic.

The research problem addressed in this paper arises from the virtualised and transient nature of 5G NFV infrastructures, which makes manual identification and classification of forensic evidence difficult, time-consuming, and error-prone (Madi et al. 2021). To overcome these limitations, there is a need for automated mechanisms capable of classifying PDE in real time to support DFR and incident response.

The objectives of this study are fourfold: (i) to develop a machine learning-based model for classifying PDE in 5G NFV environments; (ii) to evaluate the performance of supervised learning algorithms for forensic artefact classification; (iii) to analyse feature importance in order to identify forensic-relevant network characteristics; and (iv) to demonstrate how automated classification can support DFR and reporting.

The key contributions of this paper are:

- A machine learning-based PDE classification model integrated with DFR processes for 5G NFV environments.
- An empirical evaluation using hybrid datasets, combining CIC-IDS 2017 intrusion data with real 5G packet captures.
- Feature importance analysis for forensic relevance, identifying network characteristics useful for forensic investigations.

The remainder of this paper is organised as follows. Section 2 presents background and related work on 5G NFV security and DFR. Section 3 describes the research methodology and machine learning model development. Section 4 presents experimental results. Section 5 discusses findings and limitations. Section 6 concludes the paper and outlines future research directions.

2. Background and Related Works

The evolution of 5G networks has significantly enhanced communication capabilities through high bandwidth, low latency, and support for diverse services. These advancements are enabled by technologies such as Network Function Virtualisation (NFV) and network slicing, which provide scalability and flexibility but also introduce increased complexity and expanded attack surfaces. As a result, forensic investigations in 5G environments become more challenging, particularly due to the distributed and transient nature of digital evidence. Ensuring DFR through proactive evidence collection, preservation, and classification is therefore critical. While international standards provide general guidance for digital investigations, they do not fully address the challenges of virtualised 5G NFV environments. At the same time, machine learning has shown strong potential in cybersecurity, particularly for intrusion detection, but its application to forensic artefact classification remains limited. This section reviews the foundations of 5G and NFV, associated security and forensic challenges, and the role of machine learning in supporting DFR, before positioning the proposed work within existing literature.

2.1 5G Networks and Network Function Virtualisation

5G Networks represent a significant evolution in cellular communication, providing enhanced data rates, ultra-low latency, and support for massive device connectivity. These capabilities enable emerging applications such as the Internet of Things (IoT), autonomous systems, and real-time analytics (Hassan, Yau and Wu 2019).

A key architectural shift in 5G is the adoption of NFV which replaces dedicated hardware appliances with software-based Virtual Network Functions (VNFs) running on commodity hardware (Yi et al. 2018). NFV improves scalability and flexibility while reducing deployment costs. Furthermore, 5G networks employ network slicing to create multiple logical networks over shared physical infrastructure, each optimised for specific service requirements (Barakabitze et al. 2020). Despite these advantages, virtualisation introduces additional complexity and expands the attack surface, creating new challenges for cybersecurity and digital forensic investigations.

2.2 Security Challenges in 5G NFV Environments

The integration of NFV and network slicing in 5G infrastructures introduces several security risks. The virtualisation layer creates opportunities for hypervisor attacks, compromised VNFs, and cross-slice interference (Madi et al. 2021). Additionally, distributed architectures increase exposure to denial-of-service attacks, malware propagation, and insider threats (Wichary et al. 2022).

Location-shift attacks, where VNFs migrate across physical hosts, further complicate monitoring and forensic tracking of malicious activities (Yi et al. 2018). These challenges necessitate advanced detection and forensic mechanisms capable of operating in highly dynamic environments.

2.3 Digital Forensics and Digital Forensic Readiness

Digital forensics (DF) focuses on the identification, acquisition, preservation, analysis, and presentation of digital evidence following a security incident (Gogolin, 2021). This process is typically reactive, meaning evidence is collected after systems may have been altered or compromised. Digital Forensic Readiness (DFR), in contrast, adopts a proactive approach by ensuring that relevant evidence is systematically collected,

preserved, and readily available before incidents occur (Tan, 2001). Rather than replacing DF, DFR enhances the efficiency, reliability, and evidentiary value of investigations.

This distinction is particularly important in 5G NFV environments, where virtualised network functions are dynamic and distributed, and digital artefacts may be short-lived. In such contexts, reactive approaches increase the risk of evidence loss, while DFR enables continuous evidence collection and organisation to support effective post-incident analysis. ISO/IEC 27043 provides a structured framework for DFR through defined readiness processes, including planning, implementation, and assessment (Valjarević and Venter, 2016; ISO/IEC, 2015). Supporting standards such as ISO/IEC 27037 and ISO/IEC 27041 address evidence handling and investigative procedures (Ajijola, Zavarsky and Ruhl, 2014; ISO/IEC, 2012; ISO/IEC, 2016). However, these standards do not explicitly address the complexities of 5G NFV environments.

This research builds on these standards by applying DFR principles within a 5G NFV context and integrating machine learning-based classification. The proposed model aligns with ISO/IEC 27043 to ensure that automated classification of Potential Digital Evidence is both technically effective and forensically sound. standards.

2.4 Investigation Challenges in 5G NFV Environments

Forensic investigations in NFV-based 5G networks face several technical and operational challenges. Evidence sources are distributed across cloud-based infrastructure, edge devices, and virtualised network components, leading to difficulties in evidence acquisition and correlation. High-speed traffic volumes further exceed the processing capabilities of traditional forensic tools (Madi et al. 2021). Cross-domain investigations involving multiple service providers and administrative domains introduce legal and jurisdictional complexities. Moreover, the dynamic lifecycle of virtual machines and containers results in transient evidence that may be lost if not captured proactively.

2.5 Machine Learning for Cybersecurity and Digital Forensics

Machine learning techniques have been widely applied in intrusion detection, anomaly detection, and cyber threat classification. Supervised learning models such as Logistic Regression, Support Vector Machines, Random Forests, and Neural Networks have demonstrated effectiveness in detecting network attacks (Moham, Sugunaraj and Ranganathan 2022).

RF classifiers are particularly suited for tabular network traffic data due to their robustness, resistance to overfitting, and interpretability. Deep learning models such as Multilayer Perceptrons (MLP) can capture complex non-linear patterns but often require large datasets and computational resources.
